# SMALL ANIMAL INTERNAL MEDICINE

FOURTH EDITION

Richard W. Nelson C. Guillermo Couto

Grauer • Hawkins • Johnson • Lappin Scott-Moncrieff • Taylor • Ware • Watson • Willard

# Contents

# PART ONE CARDIOVASCULAR SYSTEM DISORDERS, 1

### Wendy A. Ware

- 1 Clinical Manifestations of Cardiac Disease, 1
- 2 Diagnostic Tests for the Cardiovascular System, 12
- **3** Management of Heart Failure, 53
- **4** Cardiac Arrhythmias and Antiarrhythmic Therapy, *73*
- 5 Congenital Cardiac Disease, 96
- 6 Acquired Valvular and Endocardial Disease, 114
- 7 Myocardial Diseases of the Dog, 128
- 8 Myocardial Diseases of the Cat, 142
- 9 Pericardial Disease and Cardiac Tumors, 156
- 10 Heartworm Disease, 169
- 11 Systemic Arterial Hypertension, 184
- 12 Thromboembolic Disease, 192

# PART TWO RESPIRATORY SYSTEM DISORDERS, 207

### Eleanor C. Hawkins

- 13 Clinical Manifestations of Nasal Disease, 207
- 14 Diagnostic Tests for the Nasal Cavity and Paranasal Sinuses, 213
- 15 Disorders of the Nasal Cavity, 223
- **16** Clinical Manifestations of Laryngeal and Pharyngeal Disease, 237
- 17 Diagnostic Tests for the Larynx and Pharynx, 239
- 18 Disorders of the Larynx and Pharynx, 242
- 19 Clinical Manifestations of Lower Respiratory Tract Disorders, 247
- 20 Diagnostic Tests for the Lower Respiratory Tract, 252
- 21 Disorders of the Trachea and Bronchi, 285
- **22** Disorders of the Pulmonary Parenchyma and Vasculature, *302*
- **23** Clinical Manifestations of the Pleural Cavity and Mediastinal Disease, *323*
- **24** Diagnostic Tests for the Pleural Cavity and Mediastinum, 329
- 25 Disorders of the Pleural Cavity, 335
- **26** Emergency Management of Respiratory Distress, 341
- **27** Ancillary Therapy: Oxygen Supplementation and Ventilation, *345*

# **PART THREE** DIGESTIVE SYSTEM DISORDERS, 351

### Michael D. Willard

- **28** Clinical Manifestations of Gastrointestinal Disorders, *351*
- 29 Diagnostic Tests for the Alimentary Tract, 374
- **30** General Therapeutic Principles, 395
- 31 Disorders of the Oral Cavity, Pharynx, and Esophagus, 414
- **32** Disorders of the Stomach, 427
- 33 Disorders of the Intestinal Tract, 440
- **34** Disorders of the Peritoneum, 476

# PART FOUR HEPATOBILIARY AND EXOCRINE PANCREATIC DISORDERS, 485

Penny J. Watson, Susan E. Bunch

- **35** Clinical Manifestations of Hepatobiliary Disease, 485
- **36** Diagnostic Tests for the Hepatobiliary System, 496
- **37** Hepatobiliary Diseases in the Cat, 520
- 38 Hepatobiliary Diseases in the Dog, 541
- **39** Treatment of Complications of Hepatic Disease and Failure, *569*
- 40 The Exocrine Pancreas, 579

### PART FIVE URINARY TRACT DISORDERS, 607

### Gregory F. Grauer

- 41 Clinical Manifestations of Urinary Disorders, 607
- **42** Diagnostic Tests for the Urinary System, 623
- **43** Glomerulonephropathies, 637
- **44** Acute Renal Failure and Chronic Kidney Disease, 645
- **45** Urinary Tract Infections, 660
- **46** Canine Urolithiasis, 667
- **47** Feline Lower Urinary Tract Disease, 677
- 48 Disorders of Micturition, 684

### PART SIX ENDOCRINE DISORDERS, 695

### Richard W. Nelson

**49** Disorders of the Hypothalamus and Pituitary Gland, 695

- 50 Disorders of the Parathyroid Gland, 715
- 51 Disorders of the Thyroid Gland, 724
- **52** Disorders of the Endocrine Pancreas, 764
- **53** Disorders of the Adrenal Gland, 810

# PART SEVEN METABOLIC AND ELECTROLYTE DISORDERS, 851

Richard W. Nelson, Sean J. Delaney, Denise A. Elliott

- 54 Disorders of Metabolism, 851
- **55** Electrolyte Imbalances, 864

# PART EIGHT REPRODUCTIVE SYSTEM DISORDERS, 885

### Cheri A. Johnson

- 56 Disorders of the Estrous Cycle, 885
- **57** Disorders of the Vagina and Uterus, 911
- **58** False Pregnancy, Disorders of Pregnancy and Parturition, and Mismating, 926
- 59 Postpartum and Mammary Disorders, 944
- **60** Disorders of Male Fertility, 950
- 61 Disorders of the Penis, Prepuce, and Testes, 966
- **62** Disorders of the Prostate Gland, 975

# PART NINE NEUROMUSCULAR DISORDERS, 983

### Susan M. Taylor

- **63** Lesion Localization and the Neurologic Examination, *983*
- 64 Diagnostic Tests for the Neuromuscular System, 1007
- 65 Intracranial Disorders, 1019
- **66** Loss of Vision and Pupillary Abnormalities, 1027
- **67** Seizures, 1036
- **68** Head Tilt, *1047*
- **69** Encephalitis, Myelitis, and Meningitis, 1054
- **70** Disorders of the Spinal Cord, 1065
- 71 Disorders of Peripheral Nerves and the Neuromuscular Junction, 1092
- 72 Disorders of Muscle, 1108

### PART TEN JOINT DISORDERS, 1119

### Susan M. Taylor

- **73** Clinical Manifestations of and Diagnostic Tests for Joint Disorders, 1119
- **74** Disorders of the Joints, 1127

### PART ELEVEN ONCOLOGY, 1143

### C. Guillermo Couto

- **75** Cytology, 1143
- **76** Principles of Cancer Treatment, 1150
- 77 Practical Chemotherapy, 1153
- **78** Complications of Cancer Chemotherapy, 1159
- 79 Approach to the Patient with a Mass, 1169
- **80** Lymphoma in the Cat and Dog, 1174
- **81** Leukemias, 1187
- 82 Selected Neoplasms in Dogs and Cats, 1195

### PART TWELVE HEMATOLOGY, 1209

### C. Guillermo Couto

- 83 Anemia, 1209
- **84** Erythrocytosis, 1225
- **85** Leukopenia and Leukocytosis, 1228
- **86** Combined Cytopenias and Leukoerythroblastosis, 1236
- **87** Disorders of Hemostasis, 1242
- 88 Lymphadenopathy and Splenomegaly, 1260
- **89** Hyperproteinemia, 1271
- **90** Fever of Undetermined Origin, 1274
- **91** Recurrent Infections, 1278

# PART THIRTEEN INFECTIOUS DISEASES, 1281

### Michael R. Lappin

- **92** Laboratory Diagnosis of Infectious Diseases, 1281
- 93 Practical Antimicrobial Chemotherapy, 1291
- 94 Prevention of Infectious Diseases, 1302
- 95 Polysystemic Bacterial Diseases, 1311
- **96** Polysystemic Rickettsial Diseases, 1322
- **97** Polysystemic Viral Diseases, 1336
- **98** Polysystemic Mycotic Infections, 1350
- 99 Polysystemic Protozoal Infections, 1360
- 100 Zoonoses, 1374

# PART FOURTEEN IMMUNE-MEDIATED DISORDERS, 1389

### J. Catharine Scott-Moncrieff

- Pathogenesis of Immune-Mediated Disorders, 1389
- 102 Diagnostic Testing for Autoimmune Disease, 1393
- **103** Treatment of Primary Immune-Mediated Diseases, 1398
- 104 Common Immune-Mediated Diseases, 1407

11830 Westline Industrial Drive St. Louis, Missouri 63146

### Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Authors assumes any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

# **Section Editors**

RICHARD W. NELSON, DVM, Dipl. ACVIM (Internal Medicine), Professor, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis. Dr. Nelson's interest lies in clinical endocrinology, with a special emphasis on disorders of the endocrine pancreas,

thyroid gland, and adrenal gland. Dr. Nelson has authored numerous manuscripts and book chapters, has co-authored two textbooks, *Canine and Feline Endocrinology and Reproduction* with Dr. Ed Feldman and *Small Animal Internal Medicine* with Dr. Guillermo Couto, and has lectured extensively nationally and internationally. He was an Associate Editor for the *Journal of Veterinary Internal Medicine* and serves as a reviewer for several veterinary journals. Dr. Nelson is a co-founder and member of the Society for Comparative Endocrinology and a member of the European Society of Veterinary Endocrinology.

C. GUILLERMO COUTO, DVM, Dipl. ACVIM (Internal Medicine and Oncology), Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine; Chief, Oncology/Hematology Service, Veterinary Teaching Hospital, The Ohio State University. Dr. Couto earned his doctorate at

Buenos Aires University, Argentina. In addition to his teaching responsibilities at Ohio State, Dr. Couto is the Director of the hospital's Transfusion Medicine Service and Animal Blood Bank, and of the Greyhound Health and Wellness Program. He has been Editor-in-Chief of the *Journal of Veterinary Internal Medicine* and President of the Veterinary Cancer Society. He has received the Norden Distinguished Teaching Award, the OSU Clinical Teaching Award, the BSAVA Bourgelat Award for outstanding contribution to small animal practice, and the OTS Service Award. Dr. Couto has published more than 300 articles and chapters in the areas of oncology, hematology, and immunology.

GREGORY F. GRAUER, DVM, MS, Dipl. ACVIM (Internal Medicine), Professor and Jarvis Chair of Small Animal Internal Medicine in the Department of Clinical Sciences at the College of Veterinary Medicine, Kansas State University. Dr. Grauer received his DVM degree from Iowa State Univer-

sity in 1978 and completed his postgraduate training and MS degree at Colorado State University. He was a faculty member at the University of Wisconsin for 7 years and then returned to Colorado State University, where he served as an Associate Professor and Section Chief of Small Animal Medicine until 2000. Dr. Grauer has also served as President and Chairman of the Board of Regents of the American College of Veterinary Internal Medicine. His areas of clinical and research interest involve the small animal urinary system, specifically acute and chronic renal disease. He has authored more than 225 refereed scientific publications, abstracts, and book chapters and presented more than 1100 hours of continuing education in the United States and abroad dealing with urinary tract disease in dogs and cats. He recently co-edited (with Dr. Jonathan Elliott of the Royal Veterinary College in London) the BSAVA Manual of Canine and Feline Nephrology and Urology.

ELEANOR C. HAWKINS, DVM, Dipl. ACVIM (Internal Medicine), Professor, Department of Clinical Sciences, North Carolina State University College of Veterinary Medicine. Dr. Hawkins is an officer of the Board of Regents of the American College of Veterinary Internal Medicine (ACVIM). She has served

as President of the Specialty of Small Animal Internal Medicine (ACVIM) and as a board member of the Comparative Respiratory Society. She has been invited to lecture in the United States, Europe, South America, and Japan. Dr. Hawkins is the author of many refereed publications and scientific proceedings. She has been a contributor or the respiratory editor for numerous well-known veterinary texts. Her areas of research include canine chronic bronchitis and bronchoalveolar lavage as a diagnostic tool.

CHERI A. JOHNSON, DVM, MS, Dipl. ACVIM (Internal Medicine), Professor and Chief of Staff, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University. Dr. Johnson has been an invited speaker throughout North America and Europe. Her main areas of

interest are reproduction and endocrinology. She has authored numerous scientific articles and book chapters. Dr. Johnson has served on several committees in the ACVIM, including chairing the Credentials Committee. She is a member and past Secretary/Treasurer of the Society for Comparative Endocrinology.

MICHAEL R. LAPPIN, DVM, PhD, Dipl. ACVIM (Internal Medicine), Professor of Small Animal Internal Medicine at the College of Veterinary Medicine and Biomedical Sciences at Colorado State University and Section Head of Small Animal Internal Medicine. After earning his DVM at Oklahoma State University

in 1981, he completed a small animal internal medicine residency and earned his doctorate in parasitology at the University of Georgia. Dr. Lappin has studied feline infectious diseases and has authored more than 200 research papers and book chapters. Dr. Lappin is past Associate Editor for the *Journal of Veterinary Internal Medicine* and is serving on the editorial board of *Feline Medicine and Surgery* and *Compendium for Continuing Education for the Practicing Veterinarian*. Dr. Lappin has received the Beecham Research Award and the Norden Distinguished Teaching Award, and he is the Kenneth W. Smith Professor in Small Animal Clinical Veterinary Medicine at Colorado State University.

J. CATHARINE R. SCOTT-MONCRIEFF, MA, Vet.MB, MS, Dipl. ACVIM (SA), Dipl. ECVIM (CA), Professor, Department of Veterinary Clinical Sciences, School of Veterinary Medicine, Purdue University. Dr. Scott-Moncrieff graduated from the University of Cambridge in 1985, completed an internship in

small animal medicine and surgery at the University of Saskatchewan, and a residency in internal medicine at Purdue University. In 1989 she joined the faculty of Purdue University, where she is currently Professor of small animal internal medicine and Assistant Head of the department of Veterinary Clinical Sciences. Her clinical and research interests include immune-mediated hematologic disorders and clinical endocrinology. She is the author of numerous manuscripts and book chapters and has lectured extensively nationally and internationally.

SUSAN M. TAYLOR, DVM, Dipl. ACVIM (Internal Medicine), Professor of Small Animal Medicine, Department of Small Animal Clinical Sciences, Western College of Veterinary Medicine, University of Saskatchewan. Dr. Taylor has received several awards for teaching excellence and has authored

numerous refereed journal articles and book chapters. She has been invited to present continuing education lectures throughout the United States, Canada, and Italy. Clinical, academic, and research interests include neurology, neuromuscular disease, clinical immunology, and infectious disease. Dr. Taylor has an active research program investigating medical and neurologic disorders affecting canine athletes, particularly the inherited syndrome of exercise-induced collapse in Labrador Retrievers.

WENDY A. WARE, DVM, MS, Dipl. ACVIM (Cardiology), Professor, Departments of Veterinary Clinical Sciences and Biomedical Sciences, Iowa State University. Dr. Ware has served as Clinical Cardiologist in the Veterinary Teaching Hospital and as an educator for over 20 years. Her teaching skills in

the areas of clinical cardiology and cardiovascular physiology are highly regarded. She has been invited to speak at many continuing education programs around the country and internationally. Dr. Ware has authored numerous journal articles and more than 60 book chapters. She has served as an officer on the Board of Regents of the American College of Veterinary Internal Medicine, as Associate Editor for Cardiology for the *Journal of Veterinary Internal Medicine*, and has been a reviewer for several veterinary scientific journals. Dr. Ware is a member of the AVMA and ACVIM.

PENNY J. WATSON, MA, Vet.MB, CertVR, DSAM, Dipl. ECVIM, MRCVS, Senior Lecturer in Small Animal Medicine, Queen's Veterinary School Hospital, University of Cambridge, United Kingdom. Dr. Watson received her veterinary degree from the University of Cambridge. She spent four years

in private veterinary practice in the United Kingdom before returning to Cambridge Veterinary School, where she now helps run the small animal internal medicine teaching hospital. She is both a member of the Royal College of Veterinary Surgeons and a European recognized specialist in Small Animal Internal Medicine. Dr. Watson was on the examination board of the European College of Veterinary Internal

Medicine (ECVIM) for five years, two as Chair. Her clinical and research interests are focused on gastroenterology, hepatology, pancreatic disease, and comparative metabolism. Dr. Watson is completing a doctorate by publication on aspects of chronic pancreatitis in dogs as well as supervising projects on canine chronic hepatitis. She has lectured and published widely in these areas and received the BSAVA Petsavers prize in 2008 for the best article in the *Journal of Small Animal Practice*.

MICHAEL D. WILLARD, DVM, MS, Dipl. ACVIM (Internal Medicine), Professor, Department of Veterinary Small Animal Medicine and Surgery, Texas A&M University. Dr. Willard is an internationally recognized veterinary gastroenterologist and endoscopist. He has received the National

SCAVMA teaching award for clinical teaching and the National Norden teaching award. A past President of the Comparative Gastroenterology Society and past Secretary of the specialty of Internal Medicine, his main interests are clinical gastroenterology and endoscopy (flexible and rigid). Dr. Willard has published more than 170 journal articles and book chapters on these topics and has given over 2,000 hours of invited lectures on these sub-jects in North America, Europe, South America, Asia, and Australia. A member of the International Sled Dog Veterinary Medical Association, Dr. Willard is an Associate Editor for *Journal of Veterinary Internal Medicine*.

# Contributors

SUSAN E. BUNCH, DVM, PhD, Dipl. ACVIM, formerly Professor of Medicine, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University. Dr. Bunch is currently pursuing a career outside of veterinary medicine. Previously, she was an internationally recognized vet-

erinary internist with a special interest in hepatobiliary and pancreatic disorders of cats and dogs. Related to her interest in teaching simulator technology, she was awarded a Merck-AgVet Award for Teaching Creativity in 1997 and holds a U.S. patent for the Canine Abdominal Palpation Simulator. She was a regular contributor to various journals and textbooks and was an invited reviewer for seven professional journals. Dr. Bunch was also an active member of the ACVIM and the Comparative Gastroenterology Society and Liver Study Group. She was named the NCVMA-Veterinary Teaching Hospital Clinician of the year in 1999.

SEAN J. DELANEY, DVM, MS, Dipl. ACVN, Chief Medical Officer and Senior Executive Vice President, Natura Pet Products, Inc. Dr. Delaney is a recognized expert in veterinary clinical nutrition. He received his DVM and MS in Nutrition from the University of California, Davis. He also completed

the first full-time clinical nutrition residency at UC Davis. Dr. Delaney was a clinical faculty member of the Department of Molecular Biosciences at the University of California, Davis for four years. During that time he helped develop and establish the largest veterinary clinical nutrition teaching program in the country. He also founded Davis Veterinary Medical Consulting, a pet food industry consulting firm that also maintains and supports the Balance IT® veterinary nutrition software at balanceit.com. Dr. Delaney is a frequent speaker nationally and internationally on veterinary nutrition. He is currently the Vice President of the American College of Veterinary Nutrition and is co-editing the upcoming text, *Applied Veterinary Clinical Nutrition*.

**DENISE A. ELLIOTT,** BVSc PhD, Dipl. ACVIM, ACVN, Director of Scientific Affairs, Royal Canin, USA. Dr. Elliott graduated from the University of Melbourne with a Bachelor in Veterinary Science with Honors in 1991. After completing an internship in small animal medicine and surgery at the

University of Pennsylvania, Dr. Elliott moved to the University of California, Davis where she completed a residency in small animal medicine, a fellowship in renal medicine and hemodialysis, and a residency in small animal clinical nutrition. Dr. Elliott received board certification with the American College of Veterinary Internal Medicine in 1996 and with the American College of Veterinary Nutrition in 2001. The University of California, Davis awarded her a PhD in Nutrition in 2001 for her work on multifrequency bioelectrical impedance analysis in healthy cats and dogs.

We would like to dedicate this book to Kay and Graciela.

This project would not have been possible without their continued understanding, encouragement, and patience.

# Preface

In the fourth edition of *Small Animal Internal Medicine*, we have retained our original goal of creating a practical text with a strong clinical slant that is useful for both practitioners and students. We have continued to limit authorship, with each author selected for clinical expertise in his or her respective field, to ensure as much consistency as possible within and among sections of the book. We have continued to focus on the clinically relevant aspects of the most common problems in internal medicine, presenting information in a concise, understandable, and logical format. Extensive use of tables, algorithms, cross-referencing within and among sections, and a comprehensive index help make *Small Animal Internal Medicine* a quick, easy-to-use reference textbook.

### **ORGANIZATION**

The book contains 14 sections organized by organ systems (e.g., cardiology, respiratory) or when multiple systems are involved, by discipline (e.g., oncology, infectious diseases, immune-mediated disorders). Each section, when possible, begins with a chapter on clinical signs and differential diagnoses and is followed by chapters on indications, techniques, and interpretation of diagnostic tests; general therapeutic principles; specific diseases; and finally a table listing recommended drug dosages for drugs commonly used to treat disorders within the appropriate organ system or discipline. Each section is supported extensively by tables, photographs, and schematic illustrations, including many algorithms, which address clinical presentations, differential diagnoses, diagnostic approaches, and treatment recommendations. Selected references and recommended readings are provided under the heading "Suggested Readings" at the end of each chapter. In addition, specific studies are cited in the text by author name and year of publication and are included in the Suggested Readings.

### **KEY FEATURES OF THE FOURTH EDITION**

We have retained all of the features that were popular in the first three editions, and have significantly updated and expanded the new fourth edition. New features include:

- Thoroughly revised and updated content, with expanded coverage of hundreds of topics throughout the text
- The expertise of three new authors for the sections dealing with hepatobiliary and exocrine pancreatic disorders, metabolic and electrolyte disorders, and immunemediated disorders
- New, separate sections and expanded focus on hematology and immunology

- The section focusing on immune-mediated disorders has been reorganized to include chapters on:
  - Current recommendations and interpretation of diagnostic tests
  - An overview of commonly used drugs for treating immune-mediated disorders
  - Treatment protocols for managing common immunemediated disorders
- Hundreds of new clinical photographs, the majority in full color
- Algorithms throughout the text to aid readers in the decision-making process
- Extensive cross-referencing to other chapters and discussions, providing a helpful "road map" and reducing redundancy within the book
- Hundreds of functionally color-coded summary tables and boxes to draw the reader's eye to quickly accessible information, such as:

Etiology

Differential diagnoses

Drugs (appearing within chapters)

Drug formularies (appearing at the end of each section)

Treatment

General information (e.g., formulas, clinical pathology values, manufacturer information, breed predispositions)

Finally, we are grateful to the many practitioners, faculty, and students worldwide who provided constructive comments on the first three editions, thereby making it possible to design an even stronger fourth edition. We believe the expanded content, features, and visual presentation will be positively received and will continue to make this book a valuable, user-friendly resource for all readers.

RICHARD W. NELSON C. GUILLERMO COUTO

# Acknowledgements

We would like to extend our sincerest thanks to Greg, Eleanor, Cheri, Michael, Sue, Wendy, and Mike for their continued dedication and hard work to this project; to Catharine, Penny, and Sean for their willingness to become involved in this project; and to Tony Winkel, Maureen Slaten, Celeste Clingan, and many others at Mosby for their commitment and latitude in developing this text.

# PART FOUR HEPATOBILIARY AND EXOCRINE PANCREATIC DISORDERS, 485

Penny J. Watson and Susan E. Bunch

35 Clinical Manifestations of Hepatobiliary Disease, 485
GENERAL CONSIDERATIONS, 485

ABDOMINAL ENLARGEMENT, 485
Organomegaly, 485

Abdominal Effusion, **486** Abdominal Muscular Hypotonia, **488** JAUNDICE, BILIRUBINURIA, AND CHANGE IN

FECAL COLOR, 488
HEPATIC ENCEPHALOPATHY, 491
COAGULOPATHIES, 494

POLYURIA AND POLYDIPSIA, 495

36 Diagnostic Tests for the Hepatobiliary System, 496

DIAGNOSTIC APPROACH, 496 DIAGNOSTIC TESTS, 497

Tests to Assess Status of the Hepatobiliary System, 497

Tests to Assess Function of the Hepatobiliary

System, 498

Urinalysis, 502

Fecal Evaluation, 503

Abdominocentesis/Fluid Analysis, 503

Complete Blood Count, 503

Coagulation Tests, 504

**DIAGNOSTIC IMAGING, 505** 

Survey Radiography, 505

Ultrasonography, 508

Scintigraphy, 512

LIVER BIOPSY, 513

37 Hepatobiliary Diseases in the Cat, 520 GENERAL CONSIDERATIONS, 520

HEPATIC LIPIDOSIS, 520

Primary Hepatic Lipidosis, 520

Secondary Hepatic Lipidosis, 521

**BILIARY TRACT DISEASE, 525** 

Cholangitis, 527

Cholecystitis, 531

Biliary Cysts, 532

EXTRAHEPATIC BILE DUCT OBSTRUCTION, 532 HEPATIC AMYLOIDOSIS, 532

NEOPLASIA, 534

CONGENITAL PORTOSYSTEMIC SHUNTS, 535

HEPATOBILIARY INFECTIONS, 537

TOXIC HEPATOPATHY, 538

HEPATOBILIARY INVOLVEMENT IN CATS WITH SYSTEMIC DISEASE, 539

**38** Hepatobiliary Diseases in the Dog, 541 GENERAL CONSIDERATIONS, 541

**CHRONIC HEPATITIS, 541** 

Idiopathic Chronic Hepatitis, 543

Copper Storage Disease, 548

Infectious Causes of Chronic Hepatitis, 550

Lobular Dissecting Hepatitis, 551

Toxic Causes of Chronic Hepatitis, 551

**ACUTE HEPATITIS, 552** 

**BILIARY TRACT DISORDERS, 553** 

Cholangitis and Cholecystitis, 553

Gallbladder Mucocele, 553

Extrahepatic Bile Duct Obstruction, 554

Bile Peritonitis, 555

CONGENITAL VASCULAR DISORDERS, 556

Congenital Vascular Disorders Associated with Low Portal Pressure: Congenital Portosystemic Shunt, 556

Congenital Vascular Disorders Associated with High Portal Pressure, 559

FOCAL HEPATIC LESIONS, 561

Abscesses, 561

Nodular Hyperplasia, 562

Neoplasia, 562

HEPATOCUTANEOUS SYNDROME/

SUPERFICIAL NECROLYTIC

DERMATITIS, 564

SECONDARY HEPATOPATHIES, 565

Hepatocyte Vacuolation, 565

Hepatic Congestion/Edema, 566

Nonspecific Reactive Hepatitis, 566

**39** Treatment of Complications of Hepatic Disease and Failure, 569

GENERAL CONSIDERATIONS, 569

HEPATIC ENCEPHALOPATHY, 569

Chronic Hepatic Encephalopathy, 569

Acute Hepatic Encephalopathy, 572

PORTAL HYPERTENSION, 573

Splanchnic Congestion and Gastrointestinal Ulceration, 574

Ascites, 575

COAGULOPATHY, 575

COAGULOPAI II 1, 5/5

PROTEIN-CALORIE MALNUTRITION, 577

**40** The Exocrine Pancreas, 579

**GENERAL CONSIDERATIONS, 579** 

PANCREATITIS, 579

Acute Pancreatitis, 580

Chronic Pancreatitis, 593

**EXOCRINE PANCREATIC INSUFFICIENCY, 596** 

Routine Clinical Pathology, 598

Pancreatic Enzymes, 598

Other Diagnostic Tests, 599

Drugs, 600

Diet. 600

EXOCRINE PANCREATIC NEOPLASIA, 601 PANCREATIC ABSCESSES, CYSTS, AND

PSEUDOCYSTS, 601

### PART FIVE URINARY TRACT DISORDERS, 607

### Gregory F. Grauer

**41** Clinical Manifestations of Urinary Disorders, 607 GENERAL CONSIDERATIONS, 607

Pollakiuria and Dysuria-Stranguria, 607

Urethral Obstruction, 607

Urinary Tract Infection, 608

Transitional Cell Carcinoma, 609

Urolithiasis, 609

Feline Lower Urinary Tract Disease (LUTD), 610

Hematuria, 611

DISORDERS OF MICTURITION, 614

Distended Bladder, 615

Small or Normal-Sized Bladder, 615

POLYDIPSIA AND POLYURIA, 616

PROTEINURIA, 617

AZOTEMIA, 620

RENOMEGALY, 622

**42** Diagnostic Tests for the Urinary System, 623 RENAL EXCRETORY FUNCTION, 623

Glomerular Filtration Rate, 623

Fractional Clearance, 624

QUANTIFICATION OF PROTEINURIA, 625

PLASMA AND URINE OSMOLALITY, WATER

DEPRIVATION TEST, AND RESPONSE TO

EXOGENOUS ANTIDIURETIC HORMONE, 626

BLADDER AND URETHRAL FUNCTION, 627

**BACTERIAL ANTIBIOTIC SENSITIVITY** 

TESTING, 627

DIAGNOSTIC IMAGING, 628

CYSTOSCOPY, 632

RENAL BIOPSY, 633

**43** Glomerulonephropathies, 637

**44** Acute Renal Failure and Chronic Kidney Disease, 645

ACUTE RENAL FAILURE, 646

Risk Factors for Acute Renal Damage/

Failure, 649

Monitoring Patients at Risk for Acute Renal

Damage/Failure, 650

CHRONIC KIDNEY DISEASE, 653

Staging Chronic Kidney Disease, 655

45 Urinary Tract Infections, 660

URINARY TRACT INFECTIONS, 660

Host Defense Mechanisms, 661

Complicated Versus Uncomplicated Urinary Tract

Infections, 662

Relapses Versus Reinfections, 662

46 Canine Urolithiasis, 667

GENERAL CONSIDERATIONS, 667

MONITORING THE PATIENT WITH

UROLITHIASIS, 676

47 Feline Lower Urinary Tract Disease, 677

48 Disorders of Micturition, 684

PHYSIOLOGY OF MICTURITION, 684

**DISTENDED BLADDER, 685** 

SMALL OR NORMAL-SIZE BLADDER, 687

INITIAL EVALUATION, 688

PHARMACOLOGIC TESTING, 689

LOWER MOTOR NEURON DISORDERS, 689

UPPER MOTOR NEURON DISORDERS, 689

REFLEX DYSSYNERGIA, 690

FUNCTIONAL URETHRAL OBSTRUCTION, 690

URETHRAL SPHINCTER MECHANISM

INCOMPETENCE, 690

DETRUSOR HYPERCONTRACTILITY, 691

CONGENITAL DISORDERS, 691

ANATOMIC URETHRAL OBSTRUCTION, 691

### PART SIX ENDOCRINE DISORDERS, 695

### Richard W. Nelson

**49** Disorders of the Hypothalamus and Pituitary Gland, 695

POLYURIA AND POLYDIPSIA, 695

DIABETES INSIPIDUS, 697

Central Diabetes Insipidus, 697

Nephrogenic Diabetes Insipidus, 697

Signalment, 697

Clinical Signs, 697

Physical Examination, 697

Modified Water Deprivation Test, 699

Response to Desmopressin (dDAVP), 699

Random Plasma Osmolality, 700

Additional Diagnostic Tests, 701

PRIMARY (PSYCHOGENIC) POLYDIPSIA, 702

ENDOCRINE ALOPECIA, 702

FELINE ACROMEGALY, 706

Acromegaly versus Hyperadrenocorticism, 709

PITUITARY DWARFISM, 709

Signalment, 710

Clinical Signs, 710

**50** Disorders of the Parathyroid Gland, 715

CLASSIFICATION OF

HYPERPARATHYROIDISM, 715

PRIMARY HYPERPARATHYROIDISM, 715

Signalment, 716

Clinical Signs, 716

Physical Examination, 717

PRIMARY HYPOPARATHYROIDISM, 720

Signalment, 721

Clinical Signs, 721

Physical Examination, 721

**51** Disorders of the Thyroid Gland, 724 HYPOTHYROIDISM IN DOGS, 724

Dermatologic Signs, 726

Neuromuscular Signs, 727

Reproductive Signs, 729

Miscellaneous Clinical Signs, 729

Myxedema Coma, 729

Cretinism, 729

Autoimmune Polyendocrine Syndromes, 730

## CHAPTER

# Clinical Manifestations of Cardiac Disease

### CHAPTER OUTLINE

SIGNS OF HEART DISEASE SIGNS OF HEART FAILURE

Weakness and Exercise Intolerance Syncope

Cough and Other Respiratory Signs

THE CARDIOVASCULAR EXAMINATION

Observation of Respiratory Pattern

Mucous Membranes

Jugular Veins

Arterial Pulses

Precordium

Evaluation for Fluid Accumulation

Auscultation

### SIGNS OF HEART DISEASE

Signs of heart disease can be apparent even if the animal is not clinically in "heart failure." Objective signs of heart disease include cardiac murmurs, rhythm disturbances, jugular pulsations, and cardiac enlargement. Other clinical signs that can result from heart disease include syncope, excessively weak or strong arterial pulses, cough or respiratory difficulty, exercise intolerance, abdominal distention, and cyanosis. However, noncardiac diseases can cause these signs as well. Further evaluation using thoracic radiography, electrocardiography (ECG), echocardiography, and sometimes other tests is usually indicated when signs suggestive of cardiovascular disease are present.

### SIGNS OF HEART FAILURE

Cardiac failure occurs when the heart cannot adequately meet the body's circulatory needs or can do so only with high

filling (venous) pressures. Most clinical signs of heart failure (Box 1-1) relate to high venous pressure behind the heart (congestive signs) or inadequate blood flow out of the heart (low output signs). Congestive signs associated with rightsided heart failure stem from systemic venous hypertension and the resulting increases in systemic capillary pressure. Congestion behind the left side of the heart produces pulmonary venous hypertension and edema. Biventricular failure develops in some animals. Chronic left-sided congestive heart failure can facilitate the development of rightsided signs when pulmonary arterial pressure rises secondary to pulmonary venous hypertension. Signs of low cardiac output are similar regardless of which ventricle is primarily affected, because output from the left heart is coupled to that from the right heart. Heart failure is discussed further in Chapter 3 and within the context of specific diseases.

# WEAKNESS AND EXERCISE INTOLERANCE

Cardiac output often becomes inadequate for the level of activity in animals with heart disease or failure. Impaired skeletal muscle perfusion during exercise, related to vascular and metabolic changes that occur over time, can reduce exercise tolerance. Increased pulmonary vascular pressures and edema also lead to poor exercise tolerance. Episodes of exertional weakness or collapse can relate to these changes or to an acute decrease in cardiac output caused by arrhythmias (Box 1-2).

### **SYNCOPE**

Transient unconsciousness associated with loss of postural tone (collapse) from insufficient oxygen or glucose delivery to the brain characterizes the clinical sign of syncope. Various cardiac and noncardiac abnormalities can cause syncope, as well as intermittent weakness (see Box 1-2). Syncope can be confused with seizure episodes (Fig. 1-1). A careful description of the animal's behavior or activity before the collapse event, during the event itself, and following the collapse, as

BOX 1-1

### Clinical Signs of Heart Failure

### Congestive Signs—Left († Left Heart Filling Pressure)

Pulmonary venous congestion

Pulmonary edema (causes cough, tachypnea, ↑ respiratory effort, orthopnea, pulmonary crackles, tiring, hemoptysis, cyanosis)

Secondary right-sided heart failure Cardiac arrhythmias

### Congestive Signs-Right († Right Heart Filling Pressure)

Systemic venous congestion (causes ↑ central venous pressure, jugular vein distention)

Hepatic ± splenic congestion

Pleural effusion (causes ↑ respiratory effort, orthopnea, cyanosis)

Ascites

Small pericardial effusion Subcutaneous edema Cardiac arrhythmias

### Low Output Signs

Tiring

Exertional weakness

Syncope

Prerenal azotemia

Cyanosis (from poor peripheral circulation)

Cardiac arrhythmias

### FIG 1-1

Syncope in a cat with intermittent complete AV block and delayed onset of ventricular escape rhythm. During these episodes the cat initially appeared dazed, then fell to her side and stiffened briefly. Within a few seconds she would regain consciousness and resume normal activity.

well as a drug history, helps the clinician differentiate among syncopal attacks, episodic weakness, and true seizures. Syncope is often associated with exertion or excitement. The actual event may be characterized by rear limb weakness or sudden collapse, lateral recumbency, stiffening of the forelimbs and opisthotonos, and micturition (Fig. 1-2). Vocalization is common; however, tonic/clonic motion, facial fits,

BOX 1-2

### Causes of Syncope or Intermittent Weakness

### Cardiovascular Causes

Bradyarrhythmias (second- or third-degree AV block, sinus arrest, sick sinus syndrome, atrial standstill)

Tachyarrhythmias (paroxysmal atrial or ventricular tachycardia, reentrant supraventricular tachycardia, atrial fibrillation)

Congenital ventricular outflow obstruction (pulmonic stenosis, subaortic stenosis)

Acquired ventricular outflow obstruction (heartworm disease and other causes of pulmonary hypertension, hypertrophic obstructive cardiomyopathy, intracardiac tumor, thrombus)

Cyanotic heart disease (tetralogy of Fallot, pulmonary hypertension and "reversed" shunt)

Impaired forward cardiac output (severe valvular insufficiency, dilated cardiomyopathy, myocardial infarction or inflammation)

Impaired cardiac filling (e.g., cardiac tamponade, constrictive pericarditis, hypertrophic or restrictive cardiomyopathy, intracardiac tumor, thrombus)

Cardiovascular drugs (diuretics, vasodilators)

Neurocardiogenic reflexes (vasovagal, cough-syncope, other situational syncope)

### **Pulmonary Causes**

Diseases causing hypoxemia Pulmonary hypertension Pulmonary thromboembolism

### Metabolic and Hematologic Causes

Hypoglycemia
Hypoadrenocorticism
Electrolyte imbalance (especially potassium, calcium)
Anemia
Sudden hemorrhage

### **Neurologic Causes**

Cerebrovascular accident Brain tumor (Seizures)

### **Neuromuscular Disease**

(Narcolepsy, cataplexy)

AV. Atrioventricular.

and defecation are not. An aura (which often occurs before seizure activity), postictal dementia, and neurologic deficits are generally not seen in dogs and cats with cardiovascular syncope. Sometimes profound hypotension or asystole causes hypoxic "convulsive syncope," with seizurelike activity or twitching; these convulsive syncopal episodes are preceded by loss of muscle tone. Presyncope, wherein reduced brain perfusion (or substrate delivery) is not severe enough to cause unconsciousness, may appear as transient "wobbliness" or weakness, especially in the rear limbs.

FIG 1-2
Syncope in a Doberman Pinscher with paroxysmal ventricular tachycardia. Note the extended head and neck with stiffened forelimbs. Involuntary micturition also occurred, followed shortly by return of consciousness and normal activity.

Testing to determine the cause of intermittent weakness or syncope usually includes ECG recordings (during rest, exercise, and/or after exercise or a vagal maneuver), complete blood count (CBC), serum biochemical analysis (including electrolytes and glucose), neurologic examination, thoracic radiographs, heartworm testing, and echocardiography. Other studies for neuromuscular or neurologic disease may also be valuable. Intermittent cardiac arrhythmias not apparent on resting ECG may be uncovered by 24-hour ambulatory ECG (Holter monitor), event monitoring, or in-hospital continuous ECG monitoring.

### Cardiovascular Causes of Syncope

Various arrhythmias, ventricular outflow obstructions, cyanotic congenital heart defects, and acquired diseases leading to poor cardiac output are the usual cardiac causes of syncope. Activation of vasodepressor reflexes and excessive dosages of cardiovascular drugs can also induce syncope. Arrhythmias that provoke syncope are usually associated with very fast or very slow heart rate and can occur with or without identifiable underlying organic heart disease. Ventricular outflow obstructions provoke syncope or sudden weakness if cardiac output becomes inadequate during exercise or if high systolic pressures activate ventricular mechanoreceptors, causing inappropriate reflex bradycardia and hypotension. Both dilated cardiomyopathy and severe mitral insufficiency can cause inadequate forward cardiac output, especially during exertion. Vasodilators and diuretics may induce syncope if given in excess. Syncope caused by abnormal peripheral vascular and/or neurologic reflex responses is not well defined in animals but is thought to occur in some patients. Syncope during sudden bradycardia after a burst of sinus tachycardia has been documented, especially in small breed dogs with advanced atrioventricular (AV) valve disease; excitement often precipitates such an episode. Doberman Pinschers and Boxers may experience a similar syndrome. Postural hypotension and hypersensitivity of carotid sinus receptors may infrequently provoke syncope by inappropriate peripheral vasodilation and bradycardia.

Fainting associated with a coughing fit (cough syncope or "cough-drop") occurs in some dogs with marked left atrial enlargement and bronchial compression, as well as in dogs with primary respiratory disease. Several mechanisms have been proposed, including an acute decrease in cardiac filling and output during the cough, peripheral vasodilation after the cough, and increased cerebrospinal fluid pressure with intracranial venous compression. Severe pulmonary diseases, anemia, certain metabolic abnormalities, and primary neurologic diseases can also cause collapse resembling cardiovascular syncope.

# COUGH AND OTHER RESPIRATORY SIGNS

Congestive heart failure (CHF) in dogs results in cough, tachypnea, and dyspnea. These signs also can be associated with the pulmonary vascular disease and pneumonitis of heartworm disease in both dogs and cats. Noncardiac conditions, including diseases of the upper and lower airways, pulmonary parenchyma (including noncardiogenic pulmonary edema), pulmonary vasculature, and pleural space, as well as certain nonrespiratory conditions, also should be considered in patients with cough, tachypnea, or dyspnea (see Chapter 19).

The cough caused by cardiogenic pulmonary edema in dogs is often soft and moist, but it sometimes sounds like gagging. In contrast, cough is an unusual sign of pulmonary edema in cats. Tachypnea progressing to dyspnea occurs in both species. Pleural and pericardial effusions occasionally are associated with coughing as well. Mainstem bronchus compression caused by severe left atrial enlargement can stimulate a cough (often described as dry or hacking) in dogs with chronic mitral insufficiency, even in the absence of pulmonary edema or congestion. A heartbase tumor, enlarged hilar lymph nodes, or other masses that impinge on an airway can also mechanically stimulate coughing.

When respiratory signs are caused by heart disease, other evidence, such as generalized cardiomegaly, left atrial enlargement, pulmonary venous congestion, lung infiltrates that resolve with diuretic therapy, and/or a positive heartworm test, is usually present. The findings on physical examination, thoracic radiographs, an echocardiogram if possible, and sometimes electrocardiography help the clinician differentiate cardiac from noncardiac causes of respiratory signs.

### THE CARDIOVASCULAR EXAMINATION

The medical history (Box 1-3) is an important part of the cardiovascular evaluation that helps guide the choice of diagnostic tests by suggesting various cardiac or noncardiac diseases. The signalment is useful because some congenital and acquired abnormalities are more prevalent in certain breeds or life stages or because specific findings are common

BOX 1-3

### Important Historic Information

Signalment (age, breed, gender)?

Vaccination status?

What is the diet? Have there been any recent changes in food or water consumption?

Where was the animal obtained?

Is the pet housed indoors or out?

How much time is spent outdoors? Supervised?

What activity level is normal? Does the animal tire easily now?

Has there been any coughing? When? Describe episodes.

Has there been any excessive or unexpected panting or heavy breathing?

Has there been any vomiting or gagging? Diarrhea?
Have there been any recent changes in urinary habits?
Have there been any episodes of fainting or weakness?
Do the tongue/mucous membranes always look pink, especially during exercise?

Have there been any recent changes in attitude or activity level?

Are medications being given for this problem? What? How much? How often? Do they help?

Have medications been used in the past for this problem? What? How much? Were they effective?

in individuals of a given breed (e.g., soft cardiac ejection murmur in normal Greyhounds).

Physical evaluation of the dog or cat with suspected heart disease includes observation (e.g., attitude, posture, body condition, level of anxiety, respiratory pattern) and a general physical examination. The cardiovascular examination itself consists of evaluating the peripheral circulation (mucous membranes), systemic veins (especially the jugular veins), systemic arterial pulses (usually the femoral arteries), and the precordium (left and right chest walls over the heart); palpating or percussing for abnormal fluid accumulation (e.g., ascites, subcutaneous edema, pleural effusion); and auscultating the heart and lungs. Proficiency in the cardiovascular examination requires practice but is important for accurate patient assessment and monitoring.

# OBSERVATION OF RESPIRATORY PATTERN

Respiratory difficulty (dyspnea) usually causes the animal to appear anxious. Increased respiratory effort, flared nostrils, and often a rapid rate of breathing are evident (Fig. 1-3). Increased depth of respiration (hyperpnea) frequently results from hypoxemia, hypercarbia, or acidosis. Pulmonary edema (as well as other pulmonary infiltrates) increases lung stiffness; rapid and shallow breathing (tachypnea) results as an attempt to minimize the work of breathing. An increased resting respiratory rate is an early indicator of pulmonary edema in the absence of primary lung disease. Large-volume

FIG 1-3

Dyspnea in an older male Golden Retriever with advanced dilated cardiomyopathy and fulminant pulmonary edema. The dog appeared highly anxious, with rapid labored respirations and hypersalivation. Within minutes after this photograph, respiratory arrest occurred, but the dog was resuscitated and lived another 9 months with therapy for heart failure.

FIG 1-4

Severe dyspnea is manifested in this cat by open-mouth breathing, infrequent swallowing (drooling saliva), and reluctance to lie down. Note also the dilated pupils associated with heightened sympathetic tone.

pleural effusion or other pleural space disease (e.g., pneumothorax) generally causes exaggerated respiratory motions as an effort to expand the collapsed lungs. It is important to note whether the respiratory difficulty is more intense during a particular phase of respiration. Prolonged, labored inspiration is usually associated with upper airway disorders (obstruction), whereas prolonged expiration occurs with lower airway obstruction or pulmonary infiltrative disease (including edema). Animals with severely compromised ventilation may refuse to lie down; they stand or sit with elbows abducted to allow maximal rib expansion, and they resist being positioned in lateral or dorsal recumbency (orthopnea). Cats with dyspnea often crouch in a sternal position with elbows abducted. Open-mouth breathing is usually a sign of severe respiratory distress in cats (Fig. 1-4). The

increased respiratory rate associated with excitement, fever, fear, or pain can usually be differentiated from dyspnea by careful observation and physical examination.

### **MUCOUS MEMBRANES**

Mucous membrane color and capillary refill time (CRT) are used to evaluate peripheral perfusion. The oral mucosa is usually assessed, but caudal mucous membranes (prepuce or vagina) also can be evaluated. The CRT is assessed by applying digital pressure to blanch the membrane; color should return within 2 seconds. Slower refill times occur as a result of dehydration and other causes of decreased cardiac output because of high peripheral sympathetic tone and vasoconstriction. Pale mucous membranes result from anemia or peripheral vasoconstriction. The CRT is normal in anemic animals unless hypoperfusion is also present. However, the CRT can be difficult to assess in severely anemic animals because of the lack of color contrast. The color of the caudal membranes should be compared with that of the oral membranes in polycythemic cats and dogs for evidence of differential cyanosis. If the oral membranes are pigmented, the ocular conjunctiva can be evaluated. Box 1-4 outlines causes for abnormal mucous membrane color. Petechiae in the mucous membranes may be noticed in dogs and cats with platelet disorders (see Chapter 87). In addition, oral and ocular mucous membranes are often areas where icterus (jaundice) is first detected. A yellowish cast to these membranes should prompt further evaluation for hemolysis (see Chapter 83) or hepatobiliary disease (see Chapter 35).

### **JUGULAR VEINS**

Systemic venous and right heart filling pressures are reflected at the jugular veins. These veins should not be distended when the animal is standing with its head in a normal position (jaw parallel to the floor). Persistent jugular vein distention occurs in patients with right-sided CHF (because of high right heart filling pressure), external compression of the cranial vena cava, or jugular vein or cranial vena cava thrombosis (Fig. 1-5).

Jugular pulsations extending higher than one third of the way up the neck from the thoracic inlet also are abnormal. Sometimes the carotid pulse wave is transmitted through adjacent soft tissues, mimicking a jugular pulse in thin or excited animals. To differentiate a true jugular pulse from carotid transmission, the jugular vein is occluded lightly below the area of the visible pulse. If the pulse disappears, it is a true jugular pulsation; if the pulse continues, it is being transmitted from the carotid artery. Jugular pulse waves are related to atrial contraction and filling. Visible pulsations occur in animals with tricuspid insufficiency (after the first heart sound, during ventricular contraction), conditions causing a stiff and hypertrophied right ventricle (just before the first heart sound, during atrial contraction), or arrhythmias that cause the atria to contract against closed AV valves (so-called cannon "a" waves). Specific causes of jugular vein distention and/or pulsations are listed in Box 1-5. Impaired right ventricular filling, reduced pulmonary blood flow, or

BOX 1-4

Abnormal Mucous Membrane Color

### Pale Mucous Membranes

Anemia

Poor cardiac output/high sympathetic tone

### Injected, Brick-Red Membranes

Polycythemia (erythrocytosis)

Sepsis

Excitement

Other causes of peripheral vasodilation

### Cyanotic Mucous Membranes\*

Pulmonary parenchymal disease

Airway obstruction

Pleural space disease

Pulmonary edema

Right-to-left shunting congenital cardiac defect

Hypoventilation

Shock

Cold exposure

Methemoglobinemia

### **Differential Cyanosis**

Reversed patent ductus arteriosus (head and forelimbs receive normally oxygenated blood, but caudal part of body receives desaturated blood via the ductus, which arises from the descending aorta)

### **Icteric Mucous Membranes**

Hemolysis

Hepatobiliary disease

Biliary obstruction

tricuspid regurgitation can cause a positive hepatojugular reflux even in the absence of jugular distension or pulsations at rest. To test for this reflux, firm pressure is applied to the cranial abdomen while the animal stands quietly. This transiently increases venous return. Jugular distention that persists while abdominal pressure is applied constitutes a positive (abnormal) tests. Normal animals have little to no change in the jugular vein.

### **ARTERIAL PULSES**

The strength and regularity of the peripheral arterial pressure waves and the pulse rate are assessed by palpating the femoral or other peripheral arteries (Box 1-6). Subjective evaluation of pulse strength is based on the difference between the systolic and diastolic arterial pressures (the pulse pressure). When the difference is wide, the pulse feels strong on palpation; abnormally strong pulses are termed *hyperkinetic*. When the pressure difference is small, the pulse feels weak (hypokinetic). If the rise to maximum systolic

<sup>\*</sup> Anemic animals may not appear cyanotic even with marked hypoxemia because 5 g of desaturated hemoglobin per decaliter of blood is necessary for visible cyanosis.

FIG 1-5
Prominent jugular vein distention is seen in this cat with signs of right-sided congestive heart failure from dilated cardiomyopathy.

BOX 1-5

Causes of Jugular Vein Distention/Pulsation

### Distention Alone

Pericardial effusion/tamponade
Right atrial mass/inflow obstruction
Dilated cardiomyopathy
Cranial mediastinal mass
Jugular vein/cranial vena cava thrombosis

### Pulsation ± Distention

Tricuspid insufficiency of any cause (degenerative, cardiomyopathy, congenital, secondary to diseases causing right ventricular pressure overload)

Pulmonic stenosis
Heartworm disease
Pulmonary hypertension
Ventricular premature contractions
Complete (third-degree) heart block
Constrictive pericarditis
Hypervolemia

arterial pressure is prolonged, as with severe subaortic stenosis, the pulse also feels weak (*pulsus parvus et tardus*). Both femoral pulses should be palpated and compared; absence of pulse or a weaker pulse on one side may be caused by thromboembolism. Femoral pulses can be difficult to palpate in cats, even when normal. Often an elusive pulse can be found by gently working a fingertip toward the cat's femur in the area of the femoral triangle, where the femoral artery enters the leg between the dorsomedial thigh muscles.

BOX 1-6

### Abnormal Arterial Pulses

### **Weak Pulses**

Dilated cardiomyopathy (Sub)aortic stenosis Pulmonic stenosis Shock Dehydration

### Strong Pulses

Excitement Hyperthyroidism Fever Hypertrophic cardiomyopathy

### Very Strong, Bounding Pulses

Patent ductus arteriosus Fever/sepsis Severe aortic regurgitation

The femoral arterial pulse rate should be evaluated simultaneously with the direct heart rate, which is obtained by chest wall palpation or auscultation. Fewer femoral pulses than heartbeats constitutes a pulse deficit. Various cardiac arrhythmias induce pulse deficits by causing the heart to beat before adequate ventricular filling has occurred. Consequently, minimal or even no blood is ejected for those beats and a palpable pulse is absent. Other arterial pulse variations occur occasionally. Alternately weak then strong pulsations can result from severe myocardial failure (pulsus alternans) or from a normal heartbeat alternating with a premature beat (bigeminy), which causes reduced ventricular filling and ejection. An exaggerated decrease in systolic arterial pressure during inspiration occurs in association with cardiac tamponade; a weak arterial pulse strength (pulsus paradoxus) may be detected during inspiration in those patients.

### **PRECORDIUM**

The precordium is palpated by placing the palm and fingers of each hand on the corresponding side of the animal's chest wall over the heart. Normally the strongest impulse is felt during systole over the area of the left apex (located at approximately the fifth intercostal space near the costochondral junction). Cardiomegaly or a space-occupying mass within the chest can shift the precordial impulse to an abnormal location. Decreased intensity of the precordial impulse can be caused by obesity, weak cardiac contractions, pericardial effusion, intrathoracic masses, pleural effusion, or pneumothorax. The precordial impulse should be stronger on the left chest wall than on the right. A stronger right precordial impulse can result from right ventricular hypertrophy or displacement of the heart into the right hemithorax by a mass lesion, lung atelectasis, or chest deformity. Very loud cardiac murmurs cause palpable vibrations on the chest wall

FIG 1-6
Abdominal distention in this young Neapolitan Mastiff is caused by ascites from right heart failure. The dog had congenital tricuspid valve dysplasia with severe regurgitation.

known as a *precordial thrill*. This feels like a buzzing sensation on the hand. A precordial thrill is usually localized to the area of maximal intensity of the murmur.

# EVALUATION FOR FLUID ACCUMULATION

Right-sided CHF promotes abnormal fluid accumulation within body cavities (Fig. 1-6; see also Fig. 9-3) or, usually less noticeably, in the subcutis of dependent areas. Palpation and ballottement of the abdomen, palpation of dependent areas, and percussion of the chest in the standing animal are used to detect effusions and subcutaneous edema. Fluid accumulation secondary to right-sided heart failure is usually accompanied by abnormal jugular vein distention and/or pulsations, unless the animal's circulating blood volume is diminished by diuretic use or other cause. Hepatomegaly and/or splenomegaly may also be noted in cats and dogs with right-sided heart failure.

### **AUSCULTATION**

Thoracic auscultation is used to identify normal heart sounds, determine the presence or absence of abnormal sounds, assess heart rhythm and rate, and evaluate pulmonary sounds. Heart sounds are created by turbulent blood flow and associated vibrations in adjacent tissue during the cardiac cycle. Although many of these sounds are too low in frequency and/or intensity to be audible, others can be heard with the stethoscope or even palpated. Heart sounds are classified as transient sounds (those of short duration) and cardiac murmurs (longer sounds occurring during a normally silent part of the cardiac cycle). Cardiac murmurs and transient sounds are described using general characteristics of sound: frequency (pitch), amplitude of vibrations (intensity/loudness), duration, and quality (timbre). Sound quality is affected by the physical characteristics of the vibrating structures.

Because many heart sounds are difficult to hear, a cooperative animal and a quiet room are important during aus-

**FIG 1-7**During cardiac auscultation, respiratory noise and purring can be decreased or eliminated by gently placing a finger over one or both nostrils for brief periods of time.

cultation. The animal should be standing, if possible, so that the heart is in its normal position. Panting in dogs is discouraged by holding the animal's mouth shut. Respiratory noise can be decreased further by placing a finger over one or both nostrils for a short time. Purring in cats may be stopped by holding a finger over one or both nostrils (Fig. 1-7), waving an alcohol-soaked cotton ball near the cat's nose, or turning on a water faucet near the animal. Various other artifacts can interfere with auscultation, including respiratory clicks, air movement sounds, shivering, muscle twitching, hair rubbing against the stethoscope (crackling sounds), gastrointestinal sounds, and extraneous room noises.

The traditional stethoscope has both a stiff, flat diaphragm and a bell on the chestpiece. The diaphragm, when applied firmly to the chest wall, allows better auscultation of higher-frequency heart sounds than those of low frequency. The bell, applied lightly to the chest wall, facilitates auscultation of lower-frequency sounds such as S<sub>3</sub> and S<sub>4</sub> (see the following section on Gallop Sounds). Some stethoscopes have a single-sided chestpiece that is designed to function as a diaphragm when used with firm pressure and as a bell when used with light pressure. Ideally the stethoscope should have short double tubing and comfortable eartips. The binaural eartubes should be angled rostrally to align with the examiner's ear canals (Fig. 1-8).

Both sides of the chest should be carefully auscultated, with special attention to the valve areas (Fig. 1-9). The stethoscope is moved gradually to all areas of the chest. The examiner should concentrate on the various heart sounds, correlating them to the events of the cardiac cycle, and listen for any abnormal sounds in systole and diastole successively. The normal heart sounds ( $S_1$  and  $S_2$ ) are used as a framework for timing abnormal sounds. The point of maximal intensity (PMI) of any abnormal sounds should be located. The examiner should focus on cardiac auscultation separately from pulmonary auscultation because full assimilation of sounds from both systems simultaneously is unlikely. Pulmonary auscultation is described further in Chapter 20.

### **Transient Heart Sounds**

The heart sounds normally heard in dogs and cats are  $S_1$  (associated with closure and tensing of the AV valves and associated structures at the onset of systole) and  $S_2$  (associated with closure of the aortic and pulmonic valves following ejection). The diastolic sounds ( $S_3$  and  $S_4$ ) are not audible in normal dogs and cats. Fig. 1-10 correlates the hemodynamic events of the cardiac cycle with the ECG and timing of the heart sounds. It is important to understand these events and identify the timing of systole (between  $S_1$  and  $S_2$ ) and diastole (after  $S_2$  until the next  $S_1$ ) in the animal. The precordial impulse occurs just after  $S_1$  (systole), and the arterial pulse between  $S_1$  and  $S_2$ .

Sometimes the first  $(S_1)$  and/or second  $(S_2)$  heart sounds are altered in intensity. A loud  $S_1$  may be heard in dogs and cats with a thin chest wall, high sympathetic tone, tachycar-

FIG 1-8

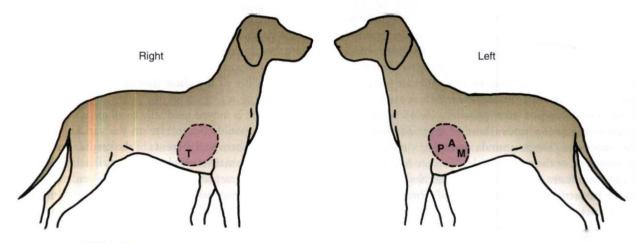

Note the angulation of the stethoscope binaurals for optimal alignment with the clinician's ear canals (Top of picture is rostral). The flat diaphragm of the chestpiece is facing left, and the concave bell is facing right.

dia, systemic arterial hypertension, or shortened PR intervals. A muffled  $S_1$  can result from obesity, pericardial effusion, diaphragmatic hernia, dilated cardiomyopathy, hypovolemia/poor ventricular filling, or pleural effusion. A split or sloppy-sounding  $S_1$  may be normal, especially in large dogs, or it may result from ventricular premature contractions or an intraventricular conduction delay. The intensity of  $S_2$  is increased by pulmonary hypertension (for example, from heartworm disease, a congenital shunt with Eisenmenger's physiology, or cor pulmonale). Cardiac arrhythmias often cause variation in the intensity (or even absence) of heart sounds.

Normal physiologic splitting of  $S_2$  can be heard in some dogs because of variation in stroke volume during the respiratory cycle. During inspiration, increased venous return to the right ventricle tends to delay closure of the pulmonic valve, while reduced filling of the left ventricle accelerates aortic closure. Pathologic splitting of  $S_2$  can result from delayed ventricular activation or prolonged right ventricular ejection secondary to ventricular premature beats, right bundle branch block, a ventricular or atrial septal defect, or pulmonary hypertension.

### **Gallop Sounds**

The third  $(S_3)$  and fourth  $(S_4)$  heart sounds occur during diastole (see Fig. 1-10) and are not normally audible in dogs and cats. When an  $S_3$  or  $S_4$  sound is heard, the heart may sound like a galloping horse, hence the term gallop rhythm. This term can be confusing because the presence or absence of an audible  $S_3$  or  $S_4$  has nothing to do with the heart's rhythm (i.e., the origin of cardiac activation and the intracardiac conduction process). Gallop sounds are usually heard best with the bell of the stethoscope (or by light pressure applied to a single-sided chestpiece) because they are of lower frequency than  $S_1$  and  $S_2$ . At very fast heart rates, differentiation of  $S_3$  from  $S_4$  is difficult. If both sounds are present, they may be superimposed, which is called a summation gallop.

Approximate locations of various valve areas on chest wall. T, Tricuspid; P, pulmonic; A, aortic; M, mitral.

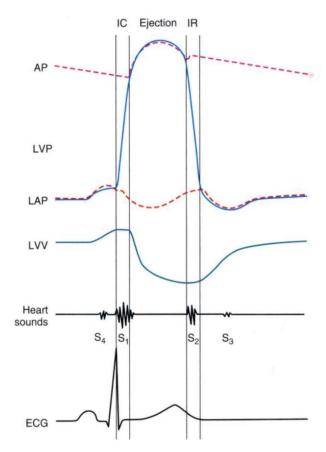

FIG 1-10

Cardiac cycle diagram depicting relationships among great vessel, ventricular and atrial pressures, ventricular volume, heart sounds, and electrical activation. AP, Aortic pressure; ECG, electrocardiogram; IC, isovolumic contraction; IR, isovolumic relaxation; LVP, left ventricular pressure; LAP, left atrial pressure; LVV, left ventricular volume.

The  $S_3$ , also known as an  $S_3$  gallop or ventricular gallop, is associated with low-frequency vibrations at the end of the rapid ventricular filling phase. An audible  $S_3$  in the dog or cat usually indicates ventricular dilation with myocardial failure. The extra sound can be fairly loud or very subtle and is heard best over the cardiac apex. It may be the only auscultable abnormality in an animal with dilated cardiomyopathy. An  $S_3$  gallop may also be audible in dogs with advanced valvular heart disease and congestive failure.

The  $S_4$  gallop, also called an *atrial* or *presystolic gallop*, is associated with low-frequency vibrations induced by blood flow into the ventricles during atrial contraction (just after the P wave of the ECG). An audible  $S_4$  in the dog or cat is usually associated with increased ventricular stiffness and hypertrophy, as with hypertrophic cardiomyopathy or hyperthyroidism in cats. A transient  $S_4$  gallop of unknown significance is sometimes heard in stressed or anemic cats.

### **Other Transient Sounds**

Other brief abnormal sounds are sometimes audible. Systolic clicks are mid-to-late systolic sounds that are usually heard

### TABLE 1-1

### Grading of Heart Murmurs

GRADE	MURMUR
1	Very soft murmur; heard only in quiet
	surroundings after prolonged listening
II	Soft murmur but easily heard
III	Moderate-intensity murmur
IV	Loud murmur but no precordial thrill
٧	Loud murmur with a palpable precordial thrill
VI	Very loud murmur with a precordial thrill; can
	be heard with the stethoscope lifted from the
	chest wall

best over the mitral valve area. These sounds have been associated with degenerative valvular disease (endocardiosis), mitral valve prolapse, and congenital mitral dysplasia; a concurrent mitral insufficiency murmur may be present. In dogs with degenerative valvular disease, a mitral click may be the first abnormal sound noted, with a murmur developing over time. An early systolic, high-pitched ejection sound at the left base may occur in animals with valvular pulmonic stenosis or other diseases that cause dilation of a great artery. The sound is thought to arise from either the sudden checking of a fused pulmonic valve or the rapid filling of a dilated vessel during ejection. Rarely, restrictive pericardial disease causes an audible pericardial knock. This diastolic sound is caused by sudden checking of ventricular filling by the restrictive pericardium; its timing is similar to the S<sub>3</sub>.

### **Cardiac Murmurs**

Cardiac murmurs are described by their timing within the cardiac cycle (systolic or diastolic, or portions thereof), intensity, PMI on the precordium, radiation over the chest wall, quality, and pitch. Systolic murmurs can occur in early (protosystolic), middle (mesosystolic), or late (telesystolic) systole or throughout systole (holosystolic). Diastolic murmurs generally occur in early diastole (protodiastolic) or throughout diastole (holodiastolic). Murmurs at the very end of diastole are termed presystolic. Continuous murmurs begin in systole and extend through S2 into all or part of diastole. Murmur intensity is arbitrarily graded on a I to VI scale (Table 1-1). The PMI is usually indicated by the hemithorax (right or left) and intercostal space or valve area where it is located, or by the terms apex or base. Because murmurs can radiate extensively, the entire thorax, thoracic inlet, and carotid artery areas should be auscultated. The pitch and quality of a murmur relate to its frequency and subjective assessment. "Noisy" or "harsh" murmurs contain mixed frequencies. "Musical" murmurs are of essentially one frequency with its overtones.

Murmurs are also described by phonocardiographic configuration (Fig. 1-11). A holosystolic (plateau-shaped) murmur begins at the time of  $S_1$  and is of fairly uniform

intensity throughout systole. Loud holosystolic murmurs may mask the  $S_1$  and  $S_2$  sounds. AV valve insufficiency and interventricular septal defects commonly cause this type of murmur because turbulent blood flour occurs throughout ventricular systole. A crescendo-decrescendo or diamond-shaped murmur starts softly, builds intensity in midsystole, and then diminishes;  $S_1$  and  $S_2$  can usually be heard clearly

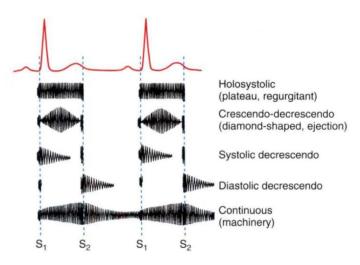

FIG 1-11
The phonocardiographic shape (configuration) as well as the timing of different murmurs are illustrated in this diagram.

before and after the murmur. This type is also called an *ejection murmur* because it occurs during blood ejection, usually because of ventricular outflow obstruction. A decrescendo murmur tapers from its initial intensity over time; it may occur in systole or diastole. Continuous (machinery) murmurs occur throughout systole and diastole.

**Systolic murmurs.** Systolic murmurs can be decrescendo, holosystolic (plateau-shaped), or ejection (crescendo-decrescendo) in configuration. It can be difficult to differentiate these by auscultation alone. But the most important steps toward diagnosis include establishing that a murmur occurs in systole (rather than diastole), determining its PMI, and grading its intensity. Fig. 1-12 depicts the typical PMI of various murmurs over the chest wall.

Functional murmurs usually are heard best over the left heartbase. They are usually soft to moderate in intensity and of decrescendo (or crescendo-decrescendo) configuration. Functional murmurs may have no apparent cardiovascular cause (e.g., "innocent" puppy murmurs) or can result from an altered physiologic state (physiologic murmurs). Innocent puppy murmurs generally disappear by the time the animal is approximately 6 months of age. Physiologic murmurs have been associated with anemia, fever, high sympathetic tone, hyperthyroidism, marked bradycardia, peripheral arteriovenous fistulae, hypoproteinemia, and athletic hearts. Aortic dilation (e.g., with hypertension) and dynamic right ventricular outflow obstruction are other conditions associated with systolic murmurs in cats.

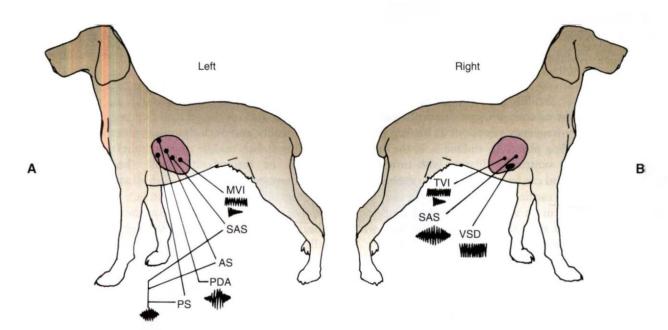

FIG 1-12

The usual point of maximal intensity (PMI) and configuration for murmurs typical of various congenital and acquired causes are depicted on left **(A)** and right **(B)** chest walls. *AS*, aortic (valvular) stenosis; *MVI*, mitral valve insufficiency; *PDA*, patent ductus arteriosus; *PS*, pulmonic stenosis; *SAS*, subaortic stenosis; *TVI*, tricuspid valve insufficiency; *VSD*, ventricular septal defect. (From Bonagura JD, Berkwitt L: Cardiovascular and pulmonary disorders. In Fenner W, editor: *Quick reference to veterinary medicine*, ed 2, Philadelphia, 1991, JB Lippincott.)

The murmur of mitral insufficiency is heard best at the left apex, in the area of the mitral valve. It radiates well dorsally and often to the left base and right chest wall. Mitral insufficiency characteristically causes a plateau-shaped murmur (holosystolic timing), but in its early stages the murmur may be protosystolic, tapering to a decrescendo configuration. Occasionally this murmur has a musical or "whoop-like" quality. With degenerative mitral valve disease, murmur intensity is related to disease severity.

Systolic ejection murmurs are most often heard at the left base and are caused by ventricular outflow obstruction, usually from a fixed narrowing (e.g., subaortic or pulmonic valve stenosis) or dynamic muscular obstruction. Ejection murmurs become louder as cardiac output or contractile strength increases. The subaortic stenosis murmur is heard well at the low left base and also at the right base because the murmur radiates up the aortic arch, which curves toward the right. This murmur also radiates up the carotid arteries and occasionally can be heard on the calvarium. Soft (grade 1-11/VI), nonpathologic systolic ejection (physiologic) murmurs are common in sight hounds and certain other large breeds; these can be related to a large stroke volume (relative aortic stenosis), as well as breed-related left ventricular outflow tract characteristics. The murmur of pulmonic stenosis is best heard high at the left base. Relative pulmonic stenosis occurs with greatly increased flow through a structurally normal valve (e.g., with a large left-to-right shunting atrial or ventricular septal defect).

Most murmurs heard on the right chest wall are holosystolic, plateau-shaped murmurs, except for the subaortic stenosis murmur (above). The tricuspid insufficiency murmur is loudest at the right apex over the tricuspid valve. Its pitch or quality may be noticeably different from a concurrent mitral insufficiency murmur, and it often is accompanied by jugular pulsations. Ventricular septal defects also cause holosystolic murmurs. The PMI is usually at the right sternal border, reflecting the direction of the intracardiac shunt. A large ventricular septal defect may also cause the murmur of relative pulmonic stenosis.

**Diastolic murmurs.** Diastolic murmurs are uncommon in dogs and cats. Aortic insufficiency from bacterial endocarditis is the most common cause, although congenital malformation or degenerative aortic valve disease occasionally occurs. Clinically relevant pulmonic insufficiency is rare but would be more likely in the face of pulmonary hypertension. These diastolic murmurs begin at the time of  $S_2$  and are heard best at the left base. They are decrescendo in configuration and extend a variable time into diastole, depending on the pressure difference between the associated great vessel and ventricle. Some aortic insufficiency murmurs have a musical quality.

**Continuous murmurs.** As implied by the name, continuous (machinery) murmurs occur throughout the cardiac cycle. They indicate that a substantial pressure gradient exists continuously between two connecting areas

(vessels). The murmur is not interrupted at the time of  $S_2$ ; instead, its intensity is often greater at that time. The murmur becomes softer toward the end of diastole, and at slow heart rates it can become inaudible. Patent ductus arteriosus (PDA) is by far the most common cause of a continuous murmur. The PDA murmur is loudest high at the left base above the pulmonic valve area; it tends to radiate cranially, ventrally, and to the right. The systolic component is usually louder and heard well all over the chest. The diastolic component is more localized to the left base in many cases. The diastolic component (and the correct diagnosis) may be missed if only the cardiac apical area is auscultated.

Continuous murmurs can be confused with concurrent systolic ejection and diastolic decrescendo murmurs. But with these so-called "to-and-fro" murmurs, the ejection (systolic) component tapers in late systole and the S<sub>2</sub> can be heard as a distinct sound. The most common cause of to-and-fro murmurs is the combination of subaortic stenosis with aortic insufficiency. Rarely, stenosis and insufficiency of the pulmonic valve cause this type of murmur. Likewise, both holosystolic and diastolic decrescendo murmurs occur occasionally (e.g., with a ventricular septal defect and aortic insufficiency from loss of aortic root support). This also is not considered a true "continuous" murmur.

# CARDIAC RADIOGRAPHY

Thoracic radiographs are important for assessing overall heart size and shape, pulmonary vessels, and lung parenchyma, as well as surrounding structures. Both lateral and dorsoventral (DV) or ventrodorsal (VD) views should be obtained. On lateral view, the ribs should be aligned with each other dorsally. On DV or VD views, the sternum, vertebral bodies, and dorsal spinous processes should be superimposed. The views chosen should be used consistently because slight changes in the appearance of the cardiac shadow occur with different positions. For example, the heart tends to look more elongated on the VD view in comparison with that on the DV view. In general, better definition of the hilar area and caudal pulmonary arteries is obtained using the DV view. High kilovoltage peak (kVp) and low milliampere (mA) radiographic technique is recommended for better resolution among soft tissue structures. Exposure is ideally made at the time of peak inspiration. On expiration, the lungs appear denser, the heart is relatively larger, the diaphragm may overlap the caudal heart border, and pulmonary vessels are poorly delineated. Use of exposure times short enough to minimize respiratory motion and proper, straight (not obliquely tilted) patient positioning are important for accurate interpretation of cardiac shape and size and pulmonary parenchyma.

The radiographs should be examined systematically, beginning with assessment of the technique, patient positioning, presence of artifacts, and phase of respiration during exposure. Chest conformation should be considered when evaluating cardiac size and shape in dogs because normal cardiac appearance may vary from breed to breed. The cardiac shadow in dogs with round or barrel-shaped chests has greater sternal contact on lateral view and an oval shape on DV or VD view. In contrast, the heart has an upright, elongated appearance on lateral view and a small, almost circular shape on DV or VD view in narrow- and deep-chested dogs. Because of variations in chest conformation and the influences of respiration, cardiac cycle, and positioning on the apparent size of the cardiac shadow, mild

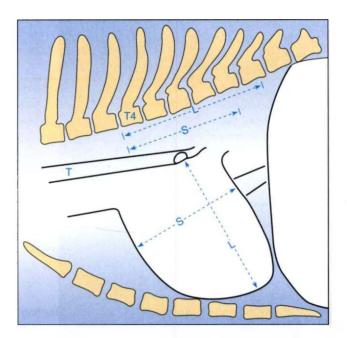

FIG 2-1

Diagram illustrating the vertebral heart score (VHS) measurement method using the lateral chest radiograph. The longaxis (L) and short-axis (S) heart dimensions are transposed onto the vertebral column and recorded as the number of vertebrae beginning with the cranial edge of T4. These values are added to obtain the VHS. In this example, L = 5.8 v, S = 4.6 v; therefore VHS = 10.4 v. T, Trachea. (Modified from Buchanan JW, Bucheler J: Vertebral scale system to measure canine heart size in radiographs, J Am Vet Med Assoc 206:194, 1995.)

cardiomegaly may be difficult to identify. Also, excess pericardial fat may mimic the appearance of cardiomegaly. The cardiac shadow in puppies normally appears slightly large relative to thoracic size compared with that of adult dogs.

The vertebral heart score (VHS) can be used as a means of quantifying the presence and degree of cardiomegaly in dogs and cats, because there is good correlation between body length and heart size regardless of chest conformation. Measurements for the VHS are obtained using the lateral view (Fig. 2-1) in adult dogs and puppies. The cardiac long axis is measured from the ventral border of the left mainstem bronchus to the most ventral aspect of the cardiac apex. This same distance is compared with the thoracic spine beginning at the cranial edge of T4; length is estimated to the nearest 0.1 vertebra. The maximum perpendicular short axis is measured in the central third of the heart shadow; the short axis is also measured in number of vertebrae (to the nearest 0.1) beginning with T4. Both measurements are added to yield the VHS. A VHS between 8.5 to 10.5 vertebrae is considered normal for most breeds. Some variation may exist among breeds; an upper limit of 11 vertebrae may be normal in dogs with a short thorax (e.g., Miniature Schnauzer), whereas an upper limit of 9.5 vertebrae may be normal in dogs with a long thorax (e.g., Dachshund). In some other breeds (e.g.,

Greyhounds), the VHS also can be above the usual reference range.

The cardiac silhouette on lateral view in cats is aligned more parallel to the sternum than in dogs; this parallel positioning may be accentuated in old cats. Radiographic positioning can influence the relative size, shape, and position of the heart because the feline thorax is so flexible. On lateral view the normal cat heart is less than or equal to two intercostal spaces (ICS) in width and less than 70% of the height of the thorax. On DV view the heart is normally no more than one half the width of the thorax. Measurement of VHS is useful in cats also. From lateral radiographs in cats, mean VHS in normal cats is 7.5 vertebrae (range 6.7 to 8.1 v). The mean short axis cardiac dimension taken from DV or VD view, compared with the thoracic spine beginning at T4 on lateral view, was 3.4 to 3.5 vertebrae. An upper limit of normal of 4 vertebrae was identified. In kittens, as in puppies, the relative size of the heart compared with that of the thorax is larger than in adults because of smaller lung volume.

An abnormally small heart shadow results from reduced venous return (e.g., from shock or hypovolemia). The apex appears more pointed and may be elevated from the sternum. Radiographic suggestion of abnormal cardiac size or shape should be considered within the context of the physical examination and other test findings.

#### CARDIOMEGALY

Generalized enlargement of the heart shadow on plain thoracic radiographs may indicate true cardiomegaly or pericardial distention. With cardiac enlargement, the contours of different chambers are usually still evident, although massive right ventricular (RV) and atrial (RA) dilation can cause a round cardiac silhouette. Fluid, fat, or viscera within the pericardium tends to obliterate these contours and create a globoid heart shadow. Common differential diagnoses for cardiac enlargement patterns are listed in Box 2-1.

# CARDIAC CHAMBER ENLARGEMENT PATTERNS

Most diseases that cause cardiac dilation or hypertrophy affect two or more chambers. For example, mitral insufficiency leads to left ventricular (LV) and left atrial (LA) enlargement; pulmonic stenosis causes RV enlargement, a main pulmonary artery bulge, and often RA dilation. For descriptive purposes, however, specific chamber and great vessel enlargements are discussed below. Fig. 2-2 illustrates various patterns of chamber enlargement.

#### **Left Atrium**

The LA is the most dorsocaudal chamber of the heart, although its auricular appendage extends to the left and craniad. An enlarged LA bulges dorsally and caudally on lateral view. There is elevation of the left and possibly right mainstem bronchi; compression of the left mainstem bronchus occurs in patients with severe LA enlargement. In cats the caudal heart border is normally quite straight on lateral view; LA enlargement causes subtle to marked convexity of

# Common Differential Diagnoses for Radiographic Signs of Cardiomegaly

#### Generalized Enlargement of the Cardiac Shadow

Dilated cardiomyopathy
Mitral and tricuspid insufficiency
Pericardial effusion
Peritoneopericardial diaphragmatic hernia
Tricuspid dysplasia
Ventricular or atrial septal defect
Patent ductus arteriosus

#### **Left Atrial Enlargement**

Early mitral insufficiency Hypertrophic cardiomyopathy Early dilated cardiomyopathy (especially Doberman Pinschers) (Sub)aortic stenosis

# Left Atrial and Ventricular Enlargement

Dilated cardiomyopathy
Hypertrophic cardiomyopathy

Mitral insufficiency Aortic insufficiency Ventricular septal defect Patent ductus arteriosus (Sub)aortic stenosis Systemic hypertension Hyperthyroidism

#### Right Atrial and Ventricular Enlargement

Advanced heartworm disease
Chronic, severe pulmonary disease
Tricuspid insufficiency
Pulmonic stenosis
Tetralogy of Fallot
Atrial septal defect
Pulmonary hypertension (with or without reversed shunting congenital defect)
Mass lesion within the right heart

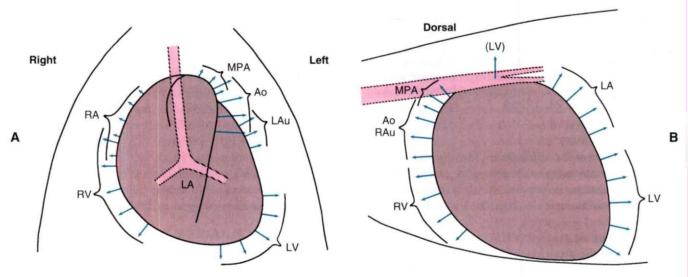

FIG 2-2

Common radiographic enlargement patterns. Diagrams indicating direction of enlargement of cardiac chambers and great vessels in the dorsoventral (A) and lateral (B) views. Ao, Aorta (descending); LA, left atrium; LAu, left auricle; LV, left ventricle; MPA, main pulmonary artery; RA, right atrium; RAu, right auricle; RV, right ventricle. (Modified from Bonagura JD, Berkwitt L: Cardiovascular and pulmonary disorders. In Fenner W, editor: Quick reference to veterinary medicine, ed 3, Philadelphia, 2000, JB Lippincott.)

the dorsocaudal heart border, with elevation of the mainstem bronchi. On DV or VD view, the mainstem bronchi are pushed laterally and curve slightly around a markedly enlarged LA (sometimes referred to as the "bowed-legged cowboy sign"). A bulge in the 2- to 3-o'clock position of the cardiac silhouette is common in cats and dogs with concurrent left auricular enlargement. Massive LA enlargement sometimes appears as a large, rounded soft tissue opacity superimposed over the LV apical area on DV (VD) view (Fig. 2-3). LA size is influenced by the pressure or volume load imposed, as well as the length of time the overload has been present. For example, mitral regurgitation of slowly increasing severity may cause massive LA enlargement without pulmonary edema if the chamber has had time to dilate at relatively low pressures. Conversely, rupture of chordae tendinae causes acute valvular regurgitation; there can be pulmonary edema with relatively normal LA size because atrial pressure rises quickly.

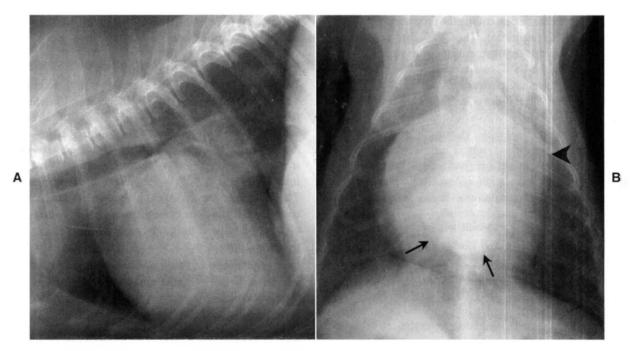

FIG 2-3
Lateral (A) and dorsoventral (B) views from a dog with chronic mitral regurgitation.
Marked left ventricular and atrial enlargement are evident. Dorsal displacement of the carina is seen in A; the caudal edge of the left atrium (arrows), superimposed over the ventricular shadow, and a prominent left auricular bulge (arrowhead) are seen in B.

# Left Ventricle

LV enlargement is manifested on lateral view by a taller cardiac silhouette with elevation of the carina and caudal vena cava. The caudal heart border becomes convex, but cardiac apical sternal contact is maintained. On DV/VD view, rounding and enlargement occur in the 2- to 5-o'clock position. Some cats with hypertrophic cardiomyopathy maintain the apical point; concurrent atrial enlargement creates the classic "valentine-shaped" heart.

#### **Right Atrium**

RA enlargement causes a bulge of the cranial heart border and widening of the cardiac silhouette on lateral view. Tracheal elevation may occur over the cranial portion of the heart shadow. Bulging of the cardiac shadow on DV/VD view occurs in the 9- to 11-o'clock position. The RA is largely superimposed over the RV; although differentiation from RV enlargement is difficult, concurrent enlargement of both chambers is common.

# **Right Ventricle**

RV enlargement (dilation or hypertrophy) usually causes increased convexity of the cranioventral heart border and elevation of the trachea over the cranial heart border on lateral view. With severe RV enlargement and relatively normal left heart size, the apex is elevated from the sternum. The carina and caudal vena cava are also elevated. The degree of sternal contact of the heart shadow is not, by itself, a reliable sign of RV enlargement because of breed variation in

chest conformation. On DV/VD view, the heart tends to take on a reverse-D configuration, especially without concurrent left-sided enlargement. The apex may be shifted leftward, and the right heart border bulges to the right.

# INTRATHORACIC BLOOD VESSELS Great Vessels

The aorta and main pulmonary artery dilate in response to chronic arterial hypertension or increased turbulence (post-stenotic dilation). Subaortic stenosis causes dilation of the ascending aorta. Because of its location within the mediastinum, dilation here is not easily detected, although widening and increased opacity of the dorsocranial heart shadow may be observed. Patent ductus arteriosus causes a localized dilation in the descending aorta just caudal to the arch, which is where the ductus exits; this "ductus bump" is seen on DV or VD view. A prominent aortic arch is more common in cats than dogs. The thoracic aorta of older cats also may have an undulating appearance. Systemic hypertension is a consideration in these cases.

Severe dilation of the main pulmonary trunk (usually associated with pulmonic stenosis or pulmonary hypertension) can be seen as a bulge superimposed over the trachea on lateral radiograph. On DV view in the dog, main pulmonary trunk enlargement causes a bulge in the 1- to 2-o'clock position. In the cat the main pulmonary trunk is slightly more medial and is usually obscured within the mediastinum.

The caudal vena cava (CaVC) normally angles cranioventrally from diaphragm to heart. The width of the CaVC is

approximately that of the descending thoracic aorta, although its size changes with respiration. The CaVC-cardiac junction is pushed dorsally with enlargement of either ventricle. Persistent widening of the CaVC could indicate right ventricular failure, cardiac tamponade, pericardial constriction, or other obstruction to right heart inflow. The following comparative findings suggest abnormal CaVC distention: CaVC/aortic diameter (at same ICS) >1.5; CaVC/length of the thoracic vertebra directly above the tracheal bifurcation >1.3; and CaVC/width of right fourth rib (just ventral to the spine) >3.5. A thin CaVC can indicate hypovolemia, poor venous return, or pulmonary overinflation.

# **Lobar Pulmonary Vessels**

Pulmonary arteries are located dorsal and lateral to their accompanying veins and bronchi. On lateral view, the cranial lobar vessels in the nondependent ("up-side") lung are more ventral and larger than those in the dependent lung. The width of the cranial lobar vessels is measured where they cross the fourth rib in dogs or at the cranial heart border (fourth to fifth rib) in cats. These vessels are normally 0.5 to 1 times the diameter of the proximal one third of the fourth rib. The DV view is best for evaluating the caudal pulmonary vessels. The caudal lobar vessels should be 0.5 to 1 times the width of the ninth (dogs) or tenth (cats) rib at the point of intersection. Four pulmonary vascular patterns are usually described: overcirculation, undercirculation, prominent pulmonary arteries, and prominent pulmonary veins.

An overcirculation pattern occurs when the lungs are hyperperfused, as in left-to-right shunts, overhydration, and other hyperdynamic states. Pulmonary arteries and veins are both prominent; the increased perfusion also generally increases lung opacity. Pulmonary undercirculation is characterized by thin pulmonary arteries and veins, along with increased pulmonary lucency. Severe dehydration, hypovolemia, obstruction to right ventricular inflow, right-sided congestive heart failure, and tetralogy of Fallot can cause this pattern. Some animals with pulmonic stenosis appear to have pulmonary undercirculation. Overinflation of the lungs or overexposure of radiographs also minimizes the appearance of pulmonary vessels.

Pulmonary arteries larger than their accompanying veins indicate pulmonary arterial hypertension. The pulmonary arteries become dilated, tortuous, and blunted, and visualization of the terminal portions is lost. Heartworm disease often causes this pulmonary vascular pattern, as well as patchy to diffuse interstitial pulmonary infiltrates.

Prominent pulmonary veins are a sign of pulmonary venous congestion, usually from left-sided congestive heart failure. On lateral view, the cranial lobar veins are larger and denser than their accompanying arteries and may sag ventrally. Dilated, tortuous pulmonary veins may be seen entering the dorsocaudal aspect of the enlarged LA in dogs and cats with chronic pulmonary venous hypertension. But pulmonary venous dilation is not always visualized in patients with left-sided heart failure. In cats with acute cardiogenic

pulmonary edema, enlargement of both pulmonary veins and arteries can be seen.

#### PATTERNS OF PULMONARY EDEMA

Pulmonary interstitial fluid accumulation increases pulmonary opacity. Pulmonary vessels appear ill-defined, and bronchial walls look thick as interstitial fluid accumulates around vessels and bronchi. As pulmonary edema worsens, areas of fluffy or mottled fluid opacity progressively become more confluent. Alveolar edema causes greater opacity in the lung fields and obscures vessels and outer bronchial walls. The air-filled bronchi appear as lucent, branching lines surrounded by fluid density (air bronchograms). Interstitial and alveolar patterns of pulmonary infiltration can be caused by many pulmonary diseases, as well as by cardiogenic edema (see Chapter 19). The distribution of these pulmonary infiltrates is important, especially in dogs. Cardiogenic pulmonary edema in dogs is classically located in dorsal and perihilar areas and is often bilaterally symmetric. Nevertheless, some dogs develop an asymmetric or concurrent ventral distribution of cardiogenic edema. The distribution of cardiogenic edema in cats is usually uneven and patchy. The infiltrates are either distributed throughout the lung fields or concentrated in the middle zones. Both the radiographic technique and the phase of respiration influence the apparent severity of interstitial infiltrates. Other abnormalities on thoracic radiographs are discussed in the Respiratory Disease section.

#### ELECTROCARDIOGRAPHY

The electrocardiogram (ECG) graphically represents the electrical depolarization and repolarization of cardiac muscle. The ECG provides information on heart rate, rhythm, and intracardiac conduction; it may also suggest the presence of specific chamber enlargement, myocardial disease, ischemia, pericardial disease, certain electrolyte imbalances, and some drug toxicities. But the ECG alone cannot be used to make a diagnosis of congestive heart failure, assess the strength (or even presence) of cardiac contractions, or predict whether the animal will survive an anesthetic or surgical procedure.

# **NORMAL ECG WAVEFORMS**

The normal cardiac rhythm originates in the sinoatrial node and activates the rest of the heart via specialized conduction pathways (Fig. 2-4). The ECG waveforms, P-QRS-T, are generated as heart muscle is depolarized and then repolarized (Fig. 2-5 and Table 2-1). The QRS complex, as a representation of ventricular muscle electrical activation, may not necessarily have each individual Q, R, or S wave components (or variations thereof). The configuration of the QRS complex depends on the lead being recorded as well as the pattern of intraventricular conduction.

# LEAD SYSTEMS

Various leads are used to evaluate the cardiac activation process. The orientation of a lead with respect to the heart

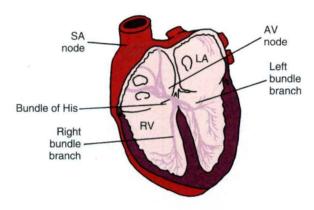

FIG 2-4

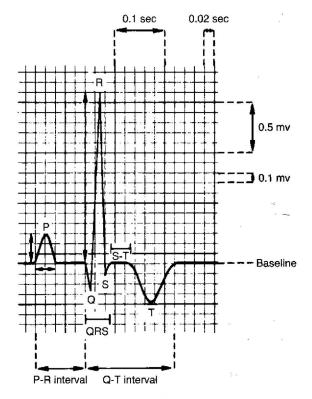

FIG 2-5
Normal canine P-QRS-T complex in lead II. Paper speed is 50 mm/sec; calibration is standard (1 cm = 1 mV). Time intervals (seconds) are measured from left to right; waveform amplitudes (millivolts) are measured as positive (upward) or negative (downward) motion from baseline. (From Tilley LE: Essentials of canine and feline electrocardiography, ed 3, Philadelphia, 1992, Lea & Febiger.)

is called the *lead axis*. Each lead has direction and polarity. If the myocardial depolarization or repolarization wave travels parallel to the lead axis, a relatively large deflection will be recorded. As the angle between the lead axis and the orientation of the activation wave increases toward 90

degrees, the ECG deflection for that lead becomes smaller; it becomes isoelectric when the activation wave is perpendicular to the lead axis. Each lead has a positive and a negative pole or direction. A positive deflection will be recorded in a lead if the cardiac activation wave travels toward the positive pole (electrode) of that lead. If the wave of depolarization travels away from the positive pole, a negative deflection will be recorded in that ECG lead. Both bipolar and unipolar ECG leads are used clinically. A bipolar lead records electrical potential differences between two electrodes on the body surface; the lead axis is oriented between these two points. (Augmented) unipolar leads have a recording electrode (positive) on the body surface. The negative pole of the unipolar leads is formed by "Wilson's central terminal" (V), which is an average of all other electrodes and is analogous to zero.

The standard limb lead system records cardiac electrical activity in the frontal plane (as depicted by a DV/VD radiograph). In this plane, left-to-right and cranial-to-caudal currents are recorded. Fig. 2-6 depicts the six standard frontal leads (hexaxial lead system) overlying the cardiac ventricles. Unipolar chest (precordial) leads "view" the heart from the transverse plane (Fig. 2-7). Box 2-2 lists common ECG lead systems.

#### APPROACH TO ECG INTERPRETATION

Routine ECG recording is usually done with the animal placed on a nonconducting surface in right lateral recumbency. The proximal limbs are parallel to each other and

perpendicular to the torso. Other body positions may change various waveform amplitudes and affect the calculated mean electrical axis (MEA). However, if only heart rate and rhythm are desired, any recording position can be used. Front limb electrodes are placed at the elbows or slightly below, not touching the chest wall or each other. Rear limb electrodes are placed at the stifles or hocks. With alligator clip or button/plate electrodes, copious ECG paste or (less ideally) alcohol is used to ensure good contact. Communication between two electrodes via a bridge of paste or alcohol or by physical contact should be avoided. The animal is gently restrained in position to minimize movement artifacts. A relaxed and quiet patient produces a better quality tracing. Holding the mouth shut to discourage panting or placing a hand on the chest of a trembling animal may be helpful.

A good ECG recording produces minimal artifact from patient movement, no electrical interference, and a clean baseline. The ECG complexes should be centered and totally contained within the background gridwork so that neither the top nor bottom of the QRS complex is clipped off. If the complexes are too large to fit entirely within the grid, the calibration should be adjusted (e.g., from standard [1 cm = 1 mV] to 1/2 standard [0.5 cm = 1 mV]). The calibration used during the recording must be known to accurately measure waveform amplitude. A calibration square wave (1 mV amplitude) can be inscribed manually during the recording if this is not done automatically. The paper speed and lead(s) recorded also must be evident for interpretation.

A consistent approach to ECG interpretation is recommended. First the paper speed, lead(s) used, and calibration are identified. Then the heart rate, heart rhythm, and MEA are determined. Finally, individual waveforms are measured. The heart rate is the number of complexes (or beats) per minute. This can be calculated by counting the number of complexes in 3 or 6 seconds and then multiplying by 20 or 10, respectively. If the heart rhythm is regular, 3000 divided by the number of small boxes (at paper speed 50 mm/sec) between successive RR intervals equals the instantaneous heart rate. Because variations in heart rate are so common (in dogs especially), determining an estimated heart rate over several seconds is usually more accurate and practical than calculating an instantaneous heart rate.

Heart rhythm is assessed by scanning the ECG for irregularities and identifying individual waveforms. The presence and pattern of P waves and QRS-T complexes are determined. The relationship between the P waves and QRS-Ts is then evaluated. Calipers are often useful for evaluating the regularity and interrelationships of the waveforms. Estimation of MEA is described on p. 28.

Individual waveforms and intervals are usually measured using lead II. Amplitudes are recorded in millivolts and durations in seconds. Only one thickness of the inscribed pen line should be included for each measurement. At 25 mm/sec paper speed, each small (1 mm) box on the ECG gridwork is 0.04 seconds in duration (from left to right). At 50 mm/sec paper speed, each small box equals 0.02 seconds.

A deflection from baseline (up or down) of 10 small boxes (1 cm) equals 1 mV at standard calibration. ECG reference ranges for cats and dogs (Table 2-2) are representative of most normal animals, although complex measurements for some subpopulations can fall outside these ranges. For example, endurance-trained dogs can have ECG measurements that exceed the "normal" range, probably reflecting the training effects on heart size. Such changes in nontrained dogs suggest pathologic cardiac enlargement. Manual frequency filters, available on many ECG machines, can markedly attenuate the recorded voltages of some waveforms when activated, although baseline artifact is reduced. The effects of filtering on QRS amplitude may complicate the assessment for ECG chamber enlargement criteria.

# SINUS RHYTHMS

The normal cardiac rhythm originates in the sinus node and produces the P-QRS-T waveforms previously described. The P waves are positive in caudal leads (II and aVF) and the PQ (or PR) intervals are consistent. Regular sinus rhythm is characterized by less than 10% variation in the timing of the QRS to QRS (or R to R) intervals. Normally the QRS complexes are narrow and upright in leads II and aVF. However, an intraventricular conduction disturbance or ventricular enlargement pattern may cause them to be wide or abnormally shaped.

Sinus arrhythmia is characterized by cyclic slowing and speeding of the sinus rate. This is usually associated with respiration; the sinus rate tends to increase on inspiration and decrease with expiration as a result of fluctuations in vagal tone. There may also be a cyclic change in P-wave configuration ("wandering pacemaker"), with the P waves becoming taller and spiked during inspiration and flatter in expiration. Sinus arrhythmia is a common and normal rhythm variation in dogs. It occurs in resting cats but is not often seen clinically. Pronounced sinus arrhythmia is associated with chronic pulmonary disease in some dogs.

"Brady-" and "tachy-" are modifying terms that describe abnormally slow or fast rhythms, respectively, without identifying intracardiac origin. Both sinus bradycardia and sinus tachycardia are rhythms that originate in the sinus node and are conducted normally; however, the rate of sinus bradycardia is slower than normal for the species, whereas that of sinus tachycardia is faster than normal. Some causes of sinus bradycardia and tachycardia are listed in Box 2-3.

Sinus arrest is absence of sinus activity lasting at least twice as long as the animal's longest expected QRS to QRS interval. An escape complex usually interrupts the resulting pause if sinus activity does not resume in time. Long pauses can cause fainting or weakness. Sinus arrest cannot be differentiated with certainty from sinoatrial (SA) block by the surface ECG. Fig. 2-8 illustrates various sinus rhythms.

# **ECTOPIC RHYTHMS**

Impulses originating from outside the sinus node (ectopic impulses) are abnormal and create an arrhythmia (dysrhythmia). Ectopic impulses are described on the basis of their

TABLE 2-2

# Normal ECG Reference Ranges for Dogs and Cats

DOGS	CATS				
Heart Rate					
70 to 160 beats/min (adults)* to 220 beats/min (puppies)	120 to 240 beats/min				
Mean Electrical Axis (Frontal Plane)					
+40 to +100 degrees	0 to +160 degrees

general site of origin (atrial, junctional, supraventricular, ventricular) and their timing (Fig. 2-9). *Timing* refers to whether the impulse occurs earlier than the next expected sinus impulse (premature) or after a longer pause (late or escape). Escape complexes represent activation of a subsidiary pacemaker and function as a rescue mechanism for the

heart. Premature ectopic impulses (complexes) occur singly or in multiples; groups of three or more constitute an episode of tachycardia. Episodes of tachycardia can be brief (paroxysmal tachycardia) or quite prolonged (sustained tachycardia). When one premature complex follows each normal QRS, a bigeminal pattern exists; the origin of the premature

<sup>\*</sup>Range may extend lower for large breeds and higher for toy breeds.
†May be greater in young (under 2 years old), thin, deep-chested dogs.

# Causes of Sinus Bradycardia and Sinus Tachycardia

#### Sinus Bradycardia

Hypothermia Hypothyroidism

Cardiac arrest (before or after)

Drugs (e.g., some tranquilizers, anesthetics, beta-blockers, calcium entry blockers, digoxin)

Increased intracranial pressure

Brainstem lesions

Severe metabolic disease (e.g., hyperkalemia, uremia)

Ocular pressure

Carotid sinus pressure

Other causes of high vagal tone (e.g., airway obstruction)

Sinus node disease

Normal variation (athletic dog)

#### Sinus Tachycardia

Hyperthermia/fever Hyperthyroidism Anemia/hypoxia

Heart failure

Shock

Hypotension

Sepsis

Anxiety/fear

Excitement

Exercise

Pain

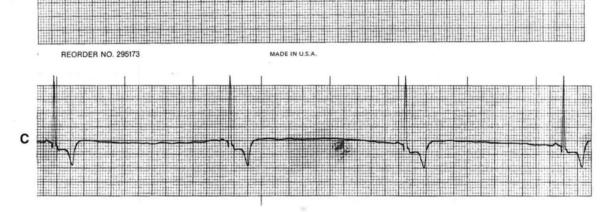

Drugs (e.g., anticholinergics, sympathomimetics)

Toxicities (e.g., chocolate, amphetamines, theophylline)

Electric shock

Other causes of high sympathetic tone

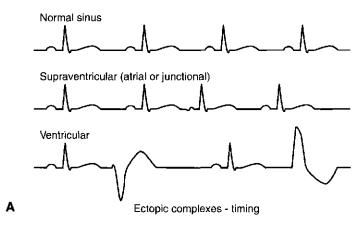

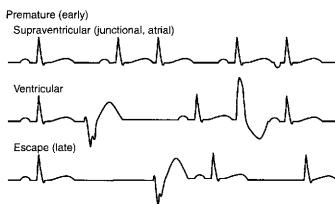

#### FIG 2-8

Sinus rhythms. **A,** Sinus rhythm in normal cat. Lead II, 25 mm/sec. **B,** Sinus arrhythmia with wandering pacemaker in a dog. Note gradual variation in P-wave height associated with respiratory changes in heart rate; this variation is normal in the dog. Lead aVF, 25 mm/sec. **C,** Sinus bradycardia. #### FIG 2-9

В

Diagrams illustrating the appearance of ectopic complexes. Abnormal impulses can originate (A) above the AV node (supraventricular) or from within the ventricles (ventricular). Supraventricular ectopic complexes have a normal-appearing QRS. An abnormal P wave usually precedes a complex originating in atrial tissue; no P wave (or a retrograde P wave in the ST segment—not shown) is common with an impulse originating from the AV junction. Ventricular-origin QRS complexes have a different configuration from the normal sinus QRS. The timing (B) of ectopic complexes refers to whether they appear before the next expected sinus complex (premature or early) or after a longer than expected pause (escape or late).

complexes determines whether the rhythm is described as atrial or ventricular bigeminy. Fig. 2-10 contains examples of supraventricular and ventricular complexes.

# Supraventricular Premature Complexes

Supraventricular premature complexes are impulses that originate above the atrioventricular (AV) node, either in the atria or the AV junctional area. Because they are conducted into and through the ventricles via the normal conduction pathway, their QRS configuration is normal (unless an intraventricular conduction disturbance is also present). Premature complexes arising within the atria are usually preceded by an abnormal P wave (positive, negative, or biphasic configuration) called a P' wave. If an ectopic P' wave occurs before the AV node has completely repolarized, the impulse may not be conducted into the ventricles (an example of physiologic AV block). In some cases, the premature impulse is conducted slowly (prolonged P'Q interval) or with a bundle

#### FIG 2-10

Ectopic complexes and rhythms. A, Atrial premature complexes in an old Cocker Spaniel with mitral insufficiency. Note small negative P waves (arrows) preceding early complexes. Slight increase in QRS size is thought to be related to minor intraventricular conduction delay with prematurity (lead III, 25 mm/sec). B, Short paroxysm of atrial tachycardia (lead II, 25 mm/sec, dog). C, Sustained atrial tachycardia in Irish Setter with mitral stenosis. Note negative, abnormal P waves (lead II, 25 mm/sec). D, Multiform ventricular premature complexes (lead II, 25 mm/sec, dog). **E,** Intermittent paroxysms of ventricular tachycardia demonstrating fusion complex (arrow) (lead II, 25 mm/sec, dog). F, Sustained ventricular tachycardia with several nonconducted P waves (arrows) superimposed (lead aVF, 25 mm/sec, dog). G, Sinus arrhythmia with periods of sinus arrest interrupted by junctional (arrows) and ventricular (arrowheads) escape complexes (lead 11, 25 mm/sec, dog). The differentiation between escape and premature complexes is crucial.

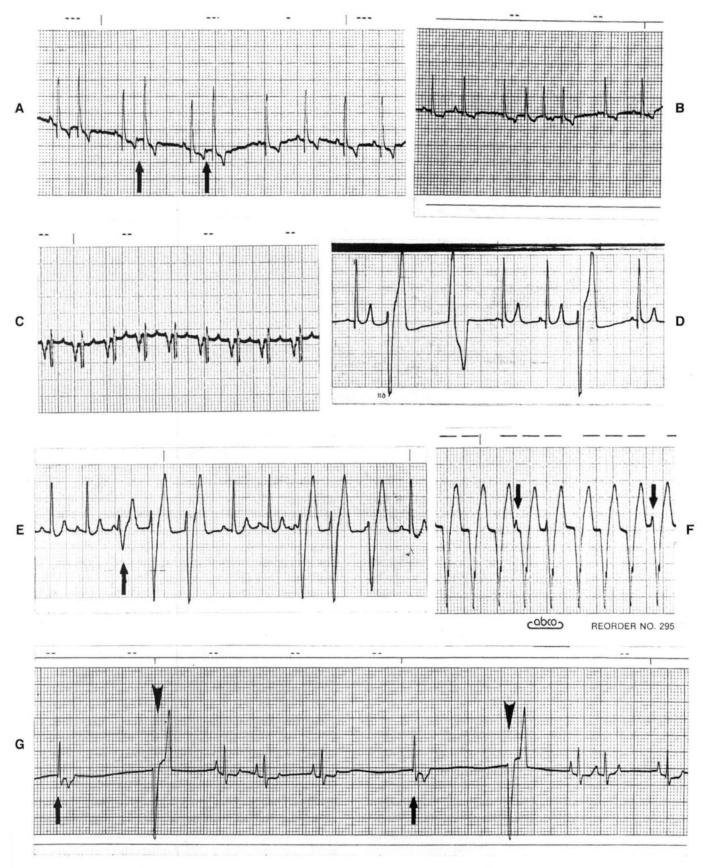

FIG 2-10
For legend, see facing page.

branch block pattern. Although P' waves usually do not precede junctional complexes, retrograde conduction into the atria sometimes causes a negative P' wave to follow, be superimposed on, or even precede the associated QRS complex. If the specific origin of the ectopic complex(es) is unclear, the more general term *supraventricular premature complex* (or *supraventricular tachycardia*) is used. Clinically it is usually more important to determine whether an arrhythmia originates from above the AV node (supraventricular) or below it (ventricular) rather than the more specific localization. Supraventricular premature complexes that also depolarize the sinus node reset the sinus rhythm and create a "noncompensatory pause" (i.e., the interval between the sinus complexes preceding and following the premature complex is less than that of three consecutive sinus complexes).

# Supraventricular Tachycardias

Tachycardias of supraventricular origin often involve a reentrant pathway using the AV node (either within the AV node or using an accessory pathway). A premature supraventricular or ventricular impulse can initiate reentrant supraventricular tachycardia (SVT). During episodes of reentrant SVT in animals with ventricular preexcitation, the PR interval usually normalizes or is prolonged, and retrograde P' waves may be evident. The QRS complexes are of normal configuration unless a simultaneous intraventricular conduction disturbance is present.

Atrial tachycardia is caused by rapid discharge of an abnormal atrial focus or by atrial reentry (repetitive activation caused by conduction of the electrical impulse around an abnormal circuit within the atria). In the dog the atrial activation rate per minute is usually between 260 and 380. The P' waves are often hidden in the QRS-T complexes. Atrial tachycardia can be paroxysmal or sustained. It is usually a regular rhythm unless the rate is too fast for the AV node to conduct every impulse, in which case physiologic AV block and irregular ventricular activation result. A consistent ratio of atrial impulses to ventricular activation (e.g., 2:1 or 3:1 AV conduction) preserves the regularity of this arrhythmia. Sometimes the impulses traverse the AV node but are delayed within the ventricular conduction system, causing a bundle branch block pattern on the ECG. Differentiation from ventricular tachycardia may be difficult in these cases.

#### **Atrial Flutter**

Atrial flutter is caused by a very rapid (usually greater than 400 impulses/min) wave of electrical activation regularly cycling through the atria. The ventricular response may be irregular or regular, depending on the pattern of AV conduction. The ECG baseline consists of "sawtooth" flutter waves that represent the fast, recurrent atrial activation. Atrial flutter is not a stable rhythm; it often degenerates into atrial fibrillation or may convert back to sinus rhythm.

# **Atrial Fibrillation**

This common arrhythmia is characterized by rapid and chaotic electrical activation within the atria. There are no P

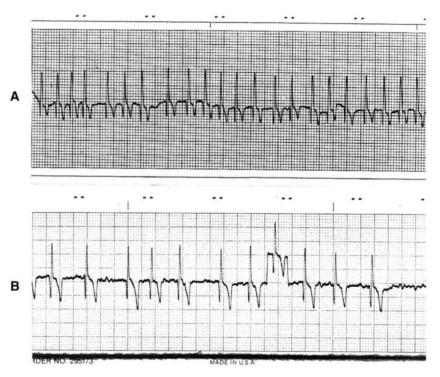

waves on the ECG because there is no uniform atrial depolarization wave. Rather, the baseline usually shows irregular undulations (fibrillation waves). Lack of organized electrical activity prevents meaningful atrial contraction. The AV node, being bombarded by chaotic electrical impulses, conducts as many as possible to the ventricles. Ultimately the (ventricular) heart rate is determined by AV conduction velocity and recovery time, which are influenced by prevailing autonomic tone. Atrial fibrillation (AF) causes an irregular heart rhythm that is often quite rapid (Fig. 2-11). The QRS complexes are usually normal in configuration because intraventricular conduction pathway is usually normal. Minor variation in QRS complex amplitude is common, however, and intermittent or sustained bundle branch blocks can occur. AF tends to be a consequence of severe atrial disease and enlargement in dogs and cats; it is usually preceded by intermittent atrial tachyarrhythmias and perhaps atrial flutter. AF sometimes occurs spontaneously in giant breed dogs without evidence of underlying heart disease ("lone" AF). The heart rate can be normal in these dogs.

# **Ventricular Premature Complexes**

Ventricular premature complexes (VPCs or PVCs) originate below the AV node and do not activate ventricular muscle via the normal ventricular conduction pathway. Therefore their QRS configuration differs from the animal's sinus complexes. Ventricular ectopic complexes are usually wider than sinus-origin complexes because of slower intramuscular conduction. Because VPCs usually are not conducted backward through the AV node into the atria, the sinus rate continues undisturbed; thus the VPC is followed by a "compensatory pause" in the sinus rhythm. When the configuration of multiple VPCs or ventricular tachycardia is consistent in an animal, the complexes are described as being uniform, unifocal, or monomorphic. When the VPCs occurring in an individual have differing configurations, they are said to be multiform or polymorphic. Increased electrical instability may accompany multiform VPCs or tachycardia.

# Ventricular Tachycardia

Ventricular tachycardia consists of a series of VPCs (usually at a rate greater than 100 beats/min). The RR interval is most often regular, although some variation can occur. Nonconducted sinus P waves may be superimposed on or between the ventricular complexes, although they are unrelated to the VPCs because the AV node and/or ventricles are in the refractory period (physiologic AV dissociation). The term capture beat refers to the successful conduction of a sinus P wave into the ventricles uninterrupted by another VPC (i.e., the sinus node has "recaptured" the ventricles). If the normal ventricular activation sequence is interrupted by a VPC, a "fusion" complex can result. A fusion complex represents a melding of the normal QRS configuration and that of the VPC (see Fig. 2-10, E). Fusion complexes are often observed at the onset or end of a paroxysm of ventricular tachycardia; they are preceded by a P wave and shortened PR interval. Identification of P waves (whether conducted or not) or

**FIG 2-11**Atrial fibrillation. **A,** Uncontrolled atrial fibrillation (heart rate 220 beats/min) in a Doberman Pinscher with dilated cardiomyopathy (lead II, 25 mm/sec). **B,** Slower ventricular response rate after therapy in a different Doberman Pinscher with dilated cardiomyopathy showing baseline fibrillation waves. Note lack of P waves and irregular RR intervals. Eighth complex from left superimposed on calibration mark. Lead II, 25 mm/sec.

fusion complexes helps in differentiating ventricular tachycardia from SVT with abnormal (aberrant) intraventricular conduction.

Polymorphic ventricular tachycardia is characterized by QRS complexes that vary in size, polarity, and often rate; sometimes the QRS configuration appears as if it were rotating around the isoelectric baseline. Torsades de pointes is a specific form of polymorphic ventricular tachycardia associated with Q-T interval prolongation.

# **Accelerated Ventricular Rhythm**

Also called *idioventricular tachycardia*, accelerated ventricular rhythm is a ventricular-origin rhythm with a rate of about 60 to 100 beats/min in the dog (perhaps somewhat faster in the cat). Because the rate is slower than true ventricular tachycardia, it is usually a less serious rhythm disturbance. An accelerated ventricular rhythm may appear intermittently during sinus arrhythmia, as the sinus rate decreases; the ventricular rhythm is often suppressed as the sinus rate increases. This is common in dogs recovering from motor vehicle trauma. Often this rhythm disturbance has no deleterious effects, although it could progress to ventricular tachycardia, especially in clinically unstable patients.

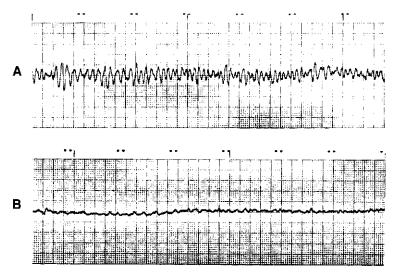

# Ventricular Fibrillation

Ventricular fibrillation is a lethal rhythm that is characterized by multiple reentrant circuits causing chaotic electrical

activity in the ventricles; the ECG consists of an irregularly undulating baseline (Fig. 2-12). The ventricles cannot function as a pump because coordinated mechanical activity cannot occur in the presence of incoordinated electrical activation. Ventricular flutter, which appears as rapid sine-wave activity on the ECG, may precede fibrillation. "Course" ventricular fibrillation (VF) has larger ECG oscillations than "fine" VF.

# **Escape Complexes**

Ventricular asystole is the absence of ventricular electrical (and mechanical) activity. Escape complexes and escape rhythms are a protective mechanism. An escape complex occurs after a pause in the dominant (usually sinus) rhythm. If the dominant rhythm does not resume, the escape focus continues to discharge at its own intrinsic rate. Escape rhythms are usually regular. Escape activity originates from automatic cells within the atria, the AV junction, or the ventricles (see Fig. 2-10, G). Ventricular escape rhythms (idioventricular rhythms) usually have an intrinsic rate less than 40 to 50 beats/min in the dog and 100 beats/min in the cat, although higher ventricular escape rates can occur. Junctional escape rhythms usually range from 40 to 60 beats/min in the dog, with a faster rate expected in the cat. It is important to differentiate escape from premature complexes. Escape activity should never be suppressed with antiarrhythmic drugs.

**FIG 2-12**Ventricular fibrillation. Note chaotic baseline motion and absence of organized waveforms. **A,** Coarse fibrillation; **B,** fine fibrillation. Lead II, 25 mm/sec, dog.

## **CONDUCTION DISTURBANCES**

Abnormal impulse conduction within the atrium can occur at several sites. With sinoatrial (SA) block, impulse transmission from the SA node to the atrial muscle is prevented. Although this cannot reliably be differentiated from sinus arrest on the ECG, with SA block the interval between P waves is a multiple of the normal P to P interval. An atrial, junctional, or ventricular escape rhythm should take over after prolonged sinus arrest or block. Atrial standstill occurs when diseased atrial muscle prevents normal electrical and mechanical function, regardless of sinus node activity; consequently, a junctional or ventricular escape rhythm results and P waves are not seen. Because hyperkalemia interferes with normal atrial function, it can mimic atrial standstill.

# Conduction Disturbances Within the AV Node

Abnormalities of AV conduction can occur from excessive vagal tone, drugs (e.g., digoxin, xylazine, medetomidine, verapamil, and anesthetic agents), and organic disease of the AV node and/or intraventricular conduction system. Three categories of AV conduction disturbances are commonly described (Fig. 2-13). First-degree AV block, the mildest, occurs when conduction from the atria into the ventricles is prolonged. All impulses are conducted, but the PR interval is longer than normal. Second-degree AV block is characterized by intermittent AV conduction; some P waves are not followed by a QRS complex. When many P waves are not conducted, the patient has high-grade second-degree heart block. There are two subtypes of second-degree AV block. Mobitz type I (Wenckebach) is characterized by progressive prolongation of the PR interval until a nonconducted P wave occurs; it is frequently associated with disorders within the AV node itself and/or high vagal tone. Mobitz type II is

characterized by uniform PR intervals preceding the blocked impulse and is thought to be more often associated with disease lower in the AV conduction system (e.g., bundle of His or major bundle branches). An alternative classification of second-degree AV block based on QRS configuration has been described. Patients with type A second-degree block have a normal, narrow QRS configuration; those with type B second-degree block have a wide or abnormal QRS configuration, which suggests diffuse disease lower in the ventricular conduction system. Mobitz type I AV block usually is type A, whereas Mobitz type II frequently is type B. Supraventricular or ventricular escape complexes are common during long pauses in ventricular activation. Third-degree or complete AV block is complete failure of AV conduction; no sinus (or supraventricular) impulses are conducted into the ventricles. Although a regular sinus rhythm or sinus arrhythmia is often evident, the P waves are not related to the QRS complexes, which result from a (usually) regular ventricular escape rhythm.

#### Intraventricular Conduction Disturbances

Abnormal (aberrant) ventricular conduction occurs in association with slowed or blocked impulse transmission in a major bundle branch or ventricular region. The right bundle branch or the left anterior or posterior fascicles of the left bundle branch can be affected singly or in combination. A block in all three major branches results in third-degree (complete) heart block. Activation of the myocardium served by the blocked pathway occurs relatively slowly, from myocyte to myocyte; therefore the QRS complexes appear wide and abnormal (Fig. 2-14). Right bundle branch block (RBBB) is sometimes identified in otherwise normal dogs and cats, although it can occur from disease or distention of the right ventricle. Left bundle branch block (LBBB) is usually related to clinically relevant underlying left ventricular disease. The

#### FIG 2-13

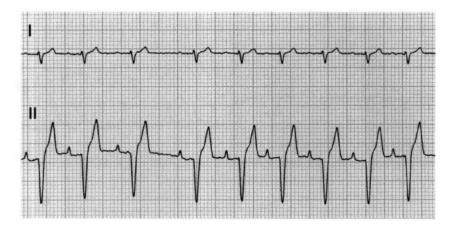

AV conduction abnormalities. **A,** First-degree AV block in a dog with digoxin toxicity (lead aVF, 25 mm/sec). **B,** Second-degree AV block (Wenckebach) in an old cat under anesthesia. Note gradually prolonged PR interval with failed conduction of third (and seventh) P wave(s) followed by an escape complex. The fourth and eighth P waves (arrows) are not conducted because the ventricles are refractory (lead II, 25 mm/sec). **C,** Second-degree AV block in a comatose old dog with brainstem signs and seizures. Note the changing configuration of the P waves (wandering pacemaker) (lead II, 25 mm/sec). **D,** Complete (third-degree) heart block in a Poodle. There is underlying sinus arrhythmia, but no P waves are conducted; a slow ventricular escape rhythm has resulted. Two calibration marks (half-standard, 0.5 cm = 1 mV) are seen. Lead II, 25 mm/sec.

left anterior fascicular block (LAFB) pattern is common in cats with hypertrophic cardiomyopathy.

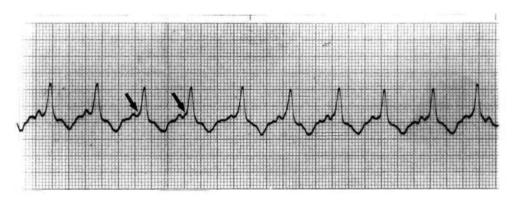

# **Ventricular Preexcitation**

Early activation (preexcitation) of part of the ventricular myocardium can occur when there is an accessory conduction pathway that bypasses the normal slow-conducting AV nodal pathway. Several types of preexcitation and accessory pathways have been described. Most cause a shortened PR interval. Wolff-Parkinson-White (WPW) preexcitation is also characterized by early widening and slurring of the QRS by a so-called delta wave (Fig. 2-15). This pattern occurs because the accessory pathway (Kent's bundle) lies outside

the AV node (extranodal) and allows early depolarization (represented by the delta wave) of a part of the ventricle distant to where normal ventricular activation begins. Other accessory pathways connect the atria or dorsal areas of the AV node directly to the bundle of His. These cause a short PR interval without early QRS widening. Preexcitation can be intermittent or concealed (not evident on ECG). The danger with preexcitation is that a reentrant supraventricular tachycardia can occur using the accessory pathway and AV node (also called AV reciprocating tachycardia). Usually the tachycardia impulses travel into the ventricles via the AV node (antegrade or orthodromic conduction) and then back to the atria via the accessory pathway, but sometimes the

**FIG 2-14** ECG from a dog that developed right bundle branch block and first-degree AV block after doxorubicin therapy. Sinus arrhythmia, Leads I and II, 25 mm/sec, 1 cm = 1 mV.

**FIG 2-15**Ventricular preexcitation in a cat. Note slowed QRS upstroke (delta wave; *arrows*) immediately following each P wave. Lead II, 50 mm/sec, 1 cm = 1 mV.

direction is reversed. Rapid AV reciprocating tachycardia can cause weakness, syncope, congestive heart failure, and death. The presence of the WPW pattern on ECG in conjunction with reentrant supraventricular tachycardia that causes clinical signs characterizes the WPW syndrome.

#### **MEAN ELECTRICAL AXIS**

The mean electrical axis (MEA) describes the average direction of the ventricular depolarization process in the frontal plane. It represents the summation of the various instantaneous vectors that occur from the beginning until the end of ventricular muscle activation. Major intraventricular conduction disturbances and/or ventricular enlargement patterns can shift the average direction of ventricular activation and therefore the MEA. Only the six frontal plane leads are used to determine MEA. Either of the following methods can be used:

1. Find the lead (I, II, III, aVR, aVL, or aVF) with the largest R wave (note: the R wave is a positive deflection). The positive electrode of this lead is the approximate orientation of the MEA.

2. Find the lead (I, II, III, aVR, aVL, or aVF) with the most isoelectric QRS (positive and negative deflections are about equal). Then identify the lead perpendicular to this lead on the hexaxial lead diagram (see Fig. 2-6). If the QRS in this perpendicular lead is mostly positive, the MEA is toward the positive pole of this lead. If the QRS in the perpendicular lead is mostly negative, the MEA is oriented toward the negative pole. If all leads appear isoelectric, the frontal axis is indeterminate. Fig. 2-6 shows the normal MEA range for dogs and cats.

# CHAMBER ENLARGEMENT AND BUNDLE BRANCH BLOCK PATTERNS

Changes in the ECG waveforms can suggest enlargement or abnormal conduction within a particular cardiac chamber. However, enlargement does not always produce these changes. A widened P wave has been associated with LA enlargement (p mitrale); sometimes the P wave is notched as well as wide. Tall, spiked P waves (p pulmonale) can accompany RA enlargement. With atrial enlargement, the usually obscure atrial repolarization (T<sub>a</sub>) wave may be

evident as a baseline shift in the opposite direction of the P wave.

A right-axis deviation and an S wave in lead I are strong criteria for RV enlargement (or RBBB). Other ECG changes can usually be found as well. Three or more of the criteria listed in Box 2-4 are generally present when right ventricular enlargement exists. RV enlargement (dilation or hypertrophy) is usually pronounced if it is evident on the ECG because LV activation forces are normally so dominant. LV dilation and eccentric hypertrophy (see Chapter 3) often increase R-wave voltage in the caudal leads (II and aVF) and widen the QRS. LV concentric hypertrophy inconsistently produces a left-axis deviation.

Conduction block in the major ventricular conduction pathways disturbs the normal activation process and alters QRS configuration. Electrical activation of ventricular muscle regions served by a diseased bundle branch occurs late and progresses slowly. This widens the QRS complex and shifts the terminal QRS orientation toward the area of delayed activation. Box 2-4 and Fig. 2-16 summarize ECG patterns associated with ventricular enlargement or conduction delay. Box 2-5 lists common clinical associations.

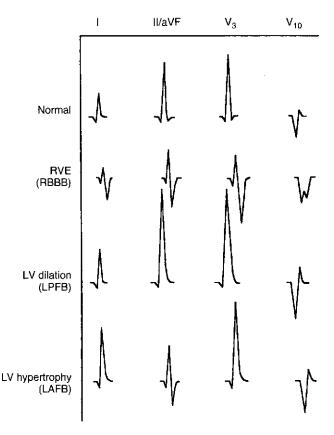

FIG 2-16

Schematic of common ventricular enlargement patterns and conduction abnormalities. ECG leads are listed across top. *LAFB*, left anterior fascicular block; *LPFB*, left posterior fascicular block; *LV*, left ventricular; *RVE*, right ventricular enlargement; *RBBB*, right bundle branch block.

#### Other QRS Abnormalities

Small-voltage QRS complexes sometimes occur. Causes of reduced QRS amplitude include pleural or pericardial effusions, obesity, intrathoracic mass lesions, hypovolemia, and hypothyroidism. Small complexes are occasionally seen in dogs without identifiable abnormalities.

Electrical alternans is an every-other-beat recurring alteration in QRS complex size or configuration. This is most often seen with large volume pericardial effusions (see Chapter 9).

#### ST-T ABNORMALITIES

The ST segment extends from the end of the QRS complex (also called the *J-point*) to the onset of the T wave. In dogs

**BOX 2-4** 

Ventricular Chamber Enlargement and Conduction Abnormality Patterns

#### Normal

Normal mean electrical axis
No S wave in lead I
R wave taller in lead II than in lead I
Lead V<sub>2</sub> R wave larger than S wave

#### Right Ventricular Enlargement

Right-axis deviation
S wave present in lead I
S wave in V<sub>23</sub> larger than R wave or >0.8 mV
Q-S (W shape) in V<sub>10</sub>
Positive T wave in lead V<sub>10</sub> (except Chihuahua breed)

Positive T wave in lead  $V_{10}$  (except Chihuahua breed) Deep S wave in leads II, III, and  $aV_F$ 

#### Right Bundle Branch Block (RBBB)

Same as right ventricular enlargement, with prolonged terminal portion of the QRS (wide, sloppy S wave)

# Left Ventricular Hypertrophy

Left-axis deviation

R wave in lead I taller than R wave in leads II or  $aV_{\text{F}}$  No S wave in lead I

#### Left Anterior Fascicular Block (LAFB)

Same as left ventricular hypertrophy, possibly with wider QRS

# Left Ventricular Dilation

Normal frontal axis

Taller than normal R wave in leads II,  $aV_F$ ,  $V_{2,3}$ 

Widened QRS; slurring and displacement of ST segment and T-wave enlargement may also occur

#### Left Bundle Branch Block (LBBB)

Normal frontal axis

Very wide and sloppy QRS

Small Q wave may be present in leads II, III, and  $aV_F$  (incomplete LBBB)

BOX 2-5

Clinical Associations of ECG Enlargement Patterns

#### Left Atrial Enlargement

Mitral insufficiency (acquired or congenital)
Cardiomyopathies
Patent ductus arteriosus
Subaortic stenosis
Ventricular septal defect

#### **Right Atrial Enlargement**

Tricuspid insufficiency (acquired or congenital) Chronic respiratory disease Interatrial septal defect Pulmonic stenosis

#### Left Ventricular Enlargement (Dilation)

Mitral insufficiency
Dilated cardiomyopathy
Aortic insufficiency
Patent ductus arteriosus
Ventricular septal defect
Subaortic stenosis

Hypertrophic cardiomyopathy Subaortic stenosis

#### **Right Ventricular Enlargement**

Pulmonic stenosis
Tetralogy of Fallot
Tricuspid insufficiency (acquired or congenital)
Severe heartworm disease
Severe pulmonary hypertension (of other cause)

and cats this segment tends to slope into the following T-wave, so clear demarcation is uncommon. Abnormal elevation (>0.15 mV in dogs or 0.1 mV in cats) or depression (>0.2 mV in dogs or >0.1 mV in cats) of the J point and ST segment in leads I, II, or aVF may be significant and can be caused by ischemia and other types of myocardial injury.

Atrial enlargement or tachycardia can cause pseudodepression of the ST segment because of prominent T<sub>a</sub> waves. Other secondary causes of ST segment deviation include ventricular hypertrophy, slowed conduction, and some drugs (e.g., digoxin).

The T wave represents ventricular muscle repolarization; it may be positive, negative, or biphasic in normal cats and dogs. Changes in size, shape, or polarity from previous recordings in a given animal are probably clinically important. Abnormalities of the T wave can be primary (i.e., not related to the depolarization process) or secondary (i.e., related to abnormalities of ventricular depolarization). Secondary ST-T changes tend to be in the opposite direction of the main QRS deflection. Box 2-6 lists some causes of ST-T abnormalities.

#### Causes of ST Segment, T Wave, and QT Abnormalities

#### Depression of J Point/ST Segment

Myocardial ischemia

Myocardial infarction/injury (subendocardial)

Hyperkalemia or hypokalemia

Cardiac trauma

Secondary change (ventricular hypertrophy, conduction disturbance, VPCs)

Digitalis ("sagging" appearance) Pseudodepression (prominent T<sub>a</sub>)

#### Elevation of the J Point/ST Segment

**Pericarditis** 

Left ventricular epicardial injury Myocardial infarction (transmural)

Myocardial hypoxia

Secondary change (ventricular hypertrophy, conduction disturbance, VPCs)

Digoxin toxicity

#### **Prolongation of QT Interval**

Hypocalcemia
Hypokalemia
Quinidine toxicity
Ethylene glycol poisoning
Secondary to prolonged QRS
Hypothermia
Central nervous system abnormalities

#### Large T Waves

Myocardial hypoxia
Ventricular enlargement
Intraventricular conduction abnormalities
Hyperkalemia
Metabolic or respiratory diseases
Normal variation

#### Tented T Waves

Hyperkalemia

VPC, Ventricular premature complex.

#### QT Interval

The QT interval represents the total time of ventricular activation and repolarization. This interval varies inversely with average heart rate; faster rates have a shorter QT interval. Autonomic nervous tone, various drugs, and electrolyte disorders influence the duration of the QT interval (see Box 2-6). Inappropriate prolongation of the QT interval may facilitate development of serious reentrant arrhythmias when underlying nonuniformity in ventricular repolariza-

tion exists. Prediction equations for expected QT duration have been derived for normal dogs and cats.

# ECG MANIFESTATIONS OF DRUG TOXICITY AND ELECTROLYTE IMBALANCE

Digoxin, antiarrhythmic agents, and anesthetic drugs often alter heart rhythm and/or conduction either by their direct electrophysiologic effects or by affecting autonomic tone (Box 2-7).

Potassium has marked and complex influences on cardiac electrophysiology. Hypokalemia can increase spontaneous automaticity of cardiac cells, as well as nonuniformly slow repolarization and conduction; these effects predispose to both supraventricular and ventricular arrhythmias. Hypokalemia can cause progressive ST segment depression, reduced T-wave amplitude, and QT interval prolongation. Severe hypokalemia can also increase QRS and P-wave amplitudes and durations. In addition, hypokalemia exacerbates digoxin toxicity and reduces the effectiveness of class I antiarrhyth-

mic agents (see Chapter 4). Hypernatremia and alkalosis worsen the effects of hypokalemia on the heart.

Moderate hyperkalemia actually has an antiarrhythmic effect by reducing automaticity and enhancing uniformity and speed of repolarization. However, rapid or severe increases in serum potassium concentration are arrhythmogenic primarily because they slow conduction velocity and shorten the refractory period. Fig. 2-17 describes the progression of ECG changes as serum potassium concentration rises. The sinus node is relatively resistant to the effects of hyperkalemia and continues to function, although often at a slower rate. Despite progressive atrial muscle unresponsiveness, specialized fibers transmit sinus impulses to the ventricles, producing a "sinoventricular" rhythm. The characteristic "tented" T-wave appearance may be more apparent in some leads than in others and may be of small amplitude. Fig. 2-18 illustrates the ECG effects of severe hyperkalemia and the response to therapy in a dog with Addison's disease. Hypocalcemia, hyponatremia, and acidosis accentuate the ECG changes caused by hyperkalemia,

BOX 2-7

ECG Changes Associated With Electrolyte Imbalance and Selected Drug Adverse Effects/Toxicity

#### Hyperkalemia (see Figs. 2-17, 2-18)

Peaked (tented) ± large T waves

Short QT interval

## Medetomidine/Xylazine

Sinus bradycardia Sinus arrest/sinoatrial block AV block

Ventricular tachyarrhythmias (especially with halothane, epinephrine)

AV, Atrioventricular.

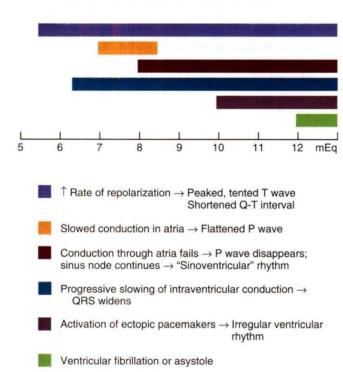

FIG 2-17

Progressive ECG changes that develop with worsening hyperkalemia (scale represents serum  $K^+$  concentration in mEq/L). Although ECG changes correlate poorly with serum  $K^+$  concentration, they accurately reflect cardiac electrophysiologic changes.

whereas hypercalcemia and hypernatremia tend to counteract them.

Marked ECG changes caused by other electrolyte disturbances are uncommon. Severe hypercalcemia or hypocalcemia could have noticeable effects (Table 2-3 on p. 34), but this is rarely seen clinically. Hypomagnesemia has no reported effects on the ECG, but it can predispose to digoxin toxicity and exaggerate the effects of hypocalcemia.

#### **COMMON ARTIFACTS**

Fig. 2-19 on p. 35 illustrates some common ECG artifacts. Electrical interference can be minimized or eliminated by properly grounding the ECG machine; turning off other electrical equipment or lights on the same circuit or having a different person restrain the animal may also help. Other artifacts are sometimes confused with arrhythmias; however, artifacts do not disturb the underlying cardiac rhythm. Conversely, ectopic complexes often disrupt the underlying rhythm and are followed by a T wave. Careful examination for these characteristics usually allows differentiation between intermittent artifacts and arrhythmias.

# **AMBULATORY ELECTROCARDIOGRAPHY**Holter Monitoring

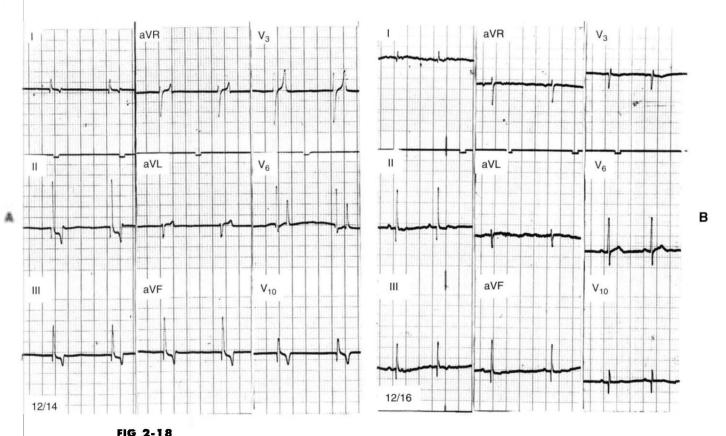

Holter monitoring allows the continuous recording of cardiac electrical activity during normal daily activities (except swimming), strenuous exercise, and sleep. This is useful for detecting and quantifying intermittent cardiac arrhythmias and therefore helps identify cardiac causes of syncope and episodic weakness. Holter monitoring is also used to assess the efficacy of antiarrhythmic drug therapy and to screen for arrhythmias associated with cardiomyopathy or other diseases. The Holter monitor is a small battery-powered digital or analog tape recorder worn by the patient, typically for 24 hours. Two or three ECG channels are recorded from modified chest leads using adhesive patch electrodes. During the recording period, the animal's activities are noted in a patient diary for later correlation with simultaneous ECG events. An event button on the Holter recorder can be pressed to mark the time a syncopal or other episode is witnessed.

The digitized recording is analyzed using computer algorithms that classify the recorded complexes. Evaluation and editing by a trained Holter technician experienced with veterinary recordings are important for accurate analysis. Fully automated computer analysis can result in significant misclassification of QRS complexes and artifacts from dog and cat recordings. A summary report and selected portions of the recording are enlarged and printed for examination by the clinician. Evaluation of a full disclosure print-out of the entire recording is also helpful when compared with the selected ECG strips and the times of clinical signs and/or activities noted in the patient diary (see Suggested Readings for more information). A Holter monitor, hook-up supplies, and analysis can be obtained from some commercial human Holter scanning services, as well as many veterinary teaching hospitals and cardiology referral centers.

Wide variation in heart rate is seen throughout the day in normal animals. In dogs maximum heart rates of up to 300 beats/min have been recorded with excitement or activity. Episodes of bradycardia (<50 beats/min) are common, especially during quiet periods and sleep. Sinus arrhythmia, sinus pauses (sometimes for more than 5 seconds), and occasional second-degree AV block are apparently common in dogs, especially at times when mean heart rate is lower. In normal cats heart rates also vary widely over 24 hours (e.g. from ~70 to ~290 beats/minute. Regular sinus rhythm predominates in normal cats, and sinus arrhythmia is evident at slower heart rates. Ventricular premature complexes occur only sporadically in normal dogs and cats; their prevalence likely increases only slightly with age.

# **Event Recording**

Cardiac event recorders are smaller than typical Holter units and contain a microprocessor with a memory loop that can store a brief period of a single modified chest lead ECG. The event recorder can be worn for periods of a week or so, but it cannot store prolonged, continuous ECG activity. Event recorders are used most often to determine whether episodic weakness or syncope is caused by a cardiac arrhythmia. When an episode is observed, the owner activates the recorder, which then stores the ECG from a predetermined time frame (e.g., from 30 seconds before activation to 30

ECGs recorded in a female Poodle with Addison's disease at presentation (**A**),  $\{K^+ = 10.2; Na^+ = 132 \text{ mEq/L}\}$ , and 2 days later after treatment (**B**),  $\{K^+ = 3.5; Na^+ = 144 \text{ mEq/L}\}$ . Note absence of P waves, accentuated and tented T waves (especially in chest leads), shortened QT interval, and slightly widened QRS complexes in **A** compared with **B**. Leads as marked, 25 mm/sec, 1 cm = 1 mV.

seconds after) for later retrieval and analysis. Implantable (subcutaneous) recording devices have also been used in some veterinary patients and can allow intermittent ECG monitoring over an extended time frame.

# OTHER METHODS OF ECG ASSESSMENT Heart Rate Variability (HRV)

Phasic fluctuations in vagal and sympathetic tone during the respiratory cycle, and also during slower periodic oscillations of arterial blood pressure, influence the variation in time between consecutive heartbeats. HRV refers to the fluctuation of beat-to-beat time intervals around their mean value. HRV is influenced by baroreceptor function as well as by the respiratory cycle and sympathetic/parasympathetic balance. The degree of HRV decreases with severe myocardial dysfunction and heart failure, as well as other causes of increased sympathetic tone. The variation in instantaneous heart rate (R-to-R intervals) can be evaluated as a function of time (time-domain analysis) as well as in terms of the frequency and amplitude of its summed oscillatory components (frequency-domain or power spectral analysis). Frequencydomain analysis allows assessment of the balance between sympathetic and vagal modulation of the cardiovascular system. The potential clinical usefulness of HRV as an indicator of autonomic function, and possibly of prognosis, for veterinary patients is being explored (see Suggested Readings).

# Signal-Averaged Electrocardiography (SAECG)

Digital signal averaging of the ECG provides a means of enhancing ECG signal resolution by discarding random components (noise) so that small-voltage potentials that may occur at the end of the QRS complex and into the early ST segment can be detected. These so-called ventricular late potentials can be found in patients with injured myocardium; they indicate the presence of conditions that predispose to reentrant ventricular tachyarrhythmias. The presence of late potentials on SAECG has been identified in some Doberman Pinschers with ventricular tachycardia and significant ventricular dysfunction, but the sensitivity for predicting risk of ventricular tachycardia is unclear (see Suggested Readings).

#### **ECHOCARDIOGRAPHY**

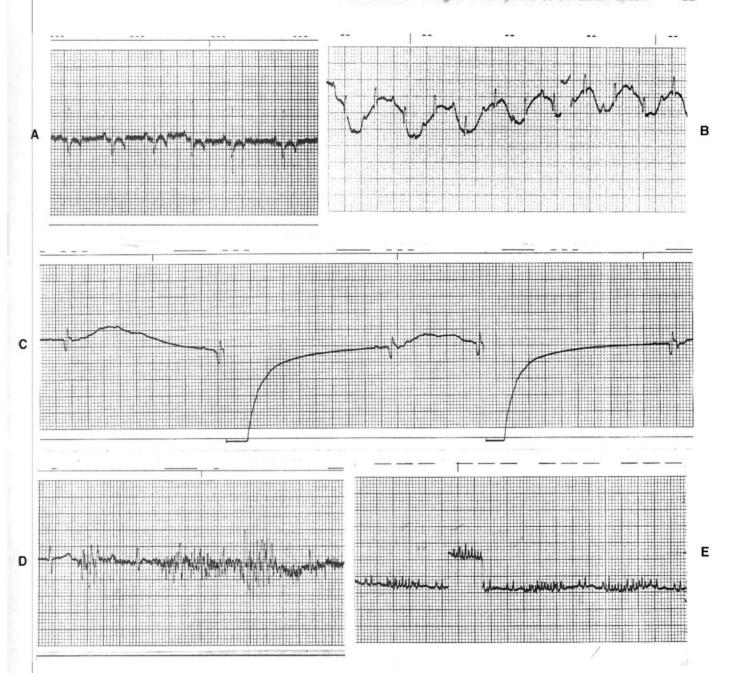

Echocardiography (cardiac ultrasonography) is an important noninvasive tool for imaging the heart and surrounding

Lead aVF, 25 mm/sec.

structures. Anatomic relationships as well as cardiac function can be assessed by evaluating cardiac chamber size, wall thickness, wall motion, valve configuration and motion, and proximal great vessels and other parameters. Pericardial and pleural fluid are easily detected, and mass lesions within and adjacent to the heart can be identified. Echocardiographic examination can usually be performed with minimal or no chemical restraint.

Like other diagnostic modalities, echocardiography is best used within the context of a thorough history, cardiovascular examination, and other appropriate tests. Technical expertise is essential to adequately perform and interpret the echocardiographic examination. The importance of the echocardiographer's skill and understanding of normal and abnormal cardiovascular anatomy and physiology cannot be overemphasized. The ultrasound equipment used as well as

individual patient characteristics also affect the quality of images obtained. Sound waves do not travel well though bone (e.g., ribs) and air (lungs); these structures may preclude good visualization of the entire heart.

# **BASIC PRINCIPLES**

Echocardiography uses pulsed, high-frequency sound waves that are reflected, refracted, and absorbed by body tissue interfaces. Only the reflected portion can be received and processed for display. Transducer frequency, power output, and various processing controls influence the intensity and clarity of the displayed echo images. Three echo modalities are used clinically: M-mode, two-dimensional (2-D, real-time), and Doppler. Each has important applications (described in the subsequent sections).

Sound waves are propagated through soft tissue at a characteristic speed (~1540 m/sec), so the thickness, size, and location of various structures in relation to the origin of the ultrasound beam can be determined at any point in time. Because the intensity of the ultrasound beam decreases as it penetrates into the body (because of beam divergence, absorption, scatter, and reflection of wave energy at tissue interfaces), echoes returning from deeper structures tend to be weaker. When the ultrasound beam (2-D and M-mode) is perpendicular to the imaged structure, stronger echos are returned. Also, greater mismatch in acoustic impedance (which is related to tissue density) between two adjacent tissues produces a more reflective boundary, and stronger echoes result. Very reflective interfaces such as bone/tissue or air/tissue interfere with imaging of weaker echos from deeper tissue interfaces.

Higher frequency ultrasound permits better resolution of small structures because of the beam characteristics of longer near field and lesser far field divergence. However, higher frequencies have less penetrating ability as more energy is absorbed and scattered by the soft tissues. Conversely, a transducer that produces lower frequencies provides greater penetration depth but less well-defined images. Frequencies generally used for small animal echocardiography range from about 3.5 MHz (for large dogs) to >10 MHz (for cats and small dogs). A megahertz (MHz) represents 1,000,000 cycles/sec.

Strongly reflective tissues are referred to as being hyperechoic or of increased echogenicity. Poorly reflecting tissues are hypoechoic; fluid, which does not reflect sound, is anechoic or sonolucent. Tissue behind an area of sonolucency appears hyperechoic because of acoustic enhancement. On the other hand, through-transmission of the ultrasound beam is blocked by a strongly hyperechoic object (such as a rib), and an acoustic shadow (where no image appears) is cast behind the object.

For most echocardiographic examinations, the animal is gently restrained in lateral recumbency; better-quality images are usually obtained when the heart is imaged from the recumbent side. For this the animal is placed on a table or platform with an edge cutout, which allows the echocardiographer to position and manipulate the transducer from the

animal's dependent side. Some animals can be adequately imaged while standing. Shaving a small area of hair over the transducer placement site can improve skin contact and image clarity. Coupling gel is applied to produce air-free contact between skin and transducer. The transducer is placed over the area of the precordial impulse (or other appropriate site), and its position is adjusted to find a good "acoustic window" that allows clear visualization of the heart. The right and left parasternal transducer positions are used most often. Minor adjustment of the animal's forelimb or torso position may be required to obtain a good acoustic window. Once the heart is located, the transducer is angled or rotated and the echocardiograph's controls for factors such as beam strength, focus, and postprocessing parameters are adjusted as necessary to optimize the image. Optimal visualization generally is achieved for 2-D and M-mode studies when the ultrasound beam is perpendicular to the cardiac structures and endocardial surfaces of interest. Image artifacts are common and can mimic a cardiac abnormality. If the suspected lesion can be visualized in more than one imaging plane, it is more likely to be real.

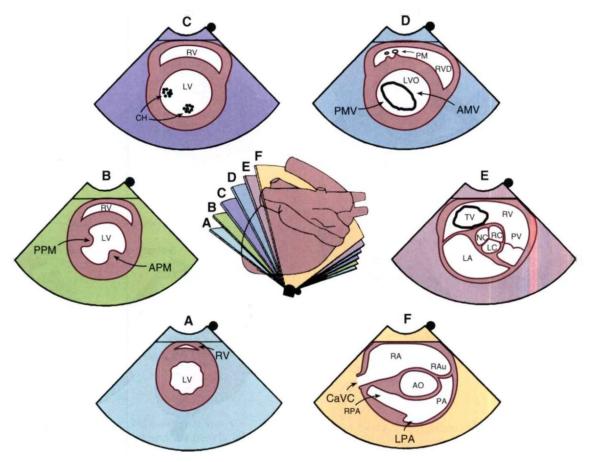

The echocardiographic examination includes carefully obtained M-mode measurements and all standard 2-D imaging planes from both sides of the chest, as well as any other views needed to further evaluate specific lesions. Doppler evaluation provides important additional information (discussed in more detail later). The complete examination can be quite time consuming in some patients. Light sedation is helpful if the animal does not lie quietly. Buprenorphine (0.0075 to 0.01 mg/kg IV) with acepromazine (0.03 mg/kg IV) usually works well for dogs. Butorphanol (0.2 mg/kg IM) with acepromazine (0.1 mg/kg IM) is adequate for many cats, although some require more intense sedation. Acepromazine (0.1 mg/kg IM) followed in 15 minutes by ketamine (2 mg/kg IV) can be used in cats, but this regimen can increase heart rate undesirably.

# TWO-DIMENSIONAL ECHOCARDIOGRAPHY

A plane of tissue (both depth and width) is displayed using 2-D echocardiography. The anatomic changes resulting from various diseases or congenital defects are evident, although actual blood flow is not usually visualized with 2-D or M-mode imaging alone.

# Common 2-D Echocardiographic Views

A variety of planes can be imaged from several chest wall locations. Most standard views are obtained from either the right or left parasternal positions (directly over the heart and close to the sternum). Images are occasionally obtained from subxiphoid (subcostal) or thoracic inlet (suprasternal) positions. Long-axis views are obtained with the imaging plane parallel to the long axis of the heart; short-axis views are perpendicular to this plane (Figs. 2-20 to 2-25). Images are described by the location of the transducer and the imaging plane used (e.g., right parasternal short-axis view, left cranial parasternal long-axis view). 2-D

# FIG 2-20

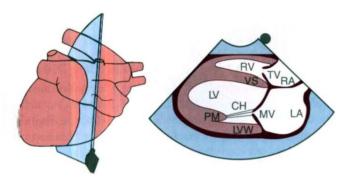

Two-dimensional short-axis echocardiographic views from the right parasternal position. The center diagram indicates the orientation of the ultrasound beam used to image cardiac structures at the six levels shown. Several of these positions guide M-mode beam placement as well as Doppler evaluation of tricuspid and pulmonary flows. Corresponding echo images are shown clockwise from the bottom. **A,** Apex. **B,** Papillary muscle. **C,** Chordae tendineae. **D,** Mitral valve. **E,** Aortic valve. **F,** Pulmonary artery. AMV, Anterior (septal) mitral valve cusp; AO, aorta; APM, anterior papillary muscle; CaVC, caudal vena cava; CH, chordae tendineae; LA, left atrium; LPA, left pulmonary artery; LV, left ventricle; LVO, left ventricular outflow tract; PA, pulmonary artery; PM, papillary muscle; PMV, posterior mitral valve cusp; PPM, posterior papillary muscle; PV, pulmonary valve; RA, right atrium; RAu, right auricle; RC, LC, NC, right, left, and noncoronary cusps of aortic valve; RPA, right pulmonary artery; RV, right ventricle; RVO, right ventricular outflow tract; TV, tricuspid valve. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

imaging allows an overall assessment of cardiac chamber orientation, size and wall thickness. The RV wall is usually about one third of the thickness of the LV free wall and should be no greater than half its thickness. The size of the right atrial and ventricular chambers is subjectively compared with that of the left atrium and ventricle; the right parasternal long axis and left apical 4 chamber views are useful for this. All valves and related structures as well as the great vessels are systematically examined. Any suspected abnormality is scanned in multiple planes to further verify and delineate it.

End diastolic and systolic LV internal dimensions and wall thickness are usually obtained using M-mode, but

appropriately timed 2-D frames can also be used. Several methods can be used to estimate LV volume and wall mass. LA size is better assessed using 2-D rather than M-mode. Several methods for measuring LA size have been described. One is to measure the cranial-caudal diameter (top-to-bottom on screen) at end-systole using a right parasternal long axis four-chamber view. In cats this LA dimension normally is <16 mm; a diameter >19 mm may indicate greater risk for thromboembolism. Because of greater body size variation in dogs, LA dimension is usually compared with the 2-D aortic root diameter measured across the sinuses of Valsalva. A 2-D maximal LA diameter:aortic root ratio between 1.7 to 1.9 is considered normal.

Long-axis 4-chamber view

Long-axis LV outflow view

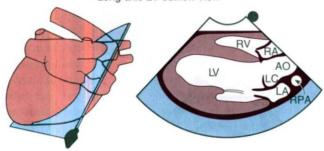

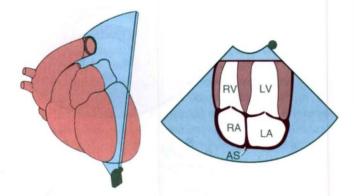

FIG 2-21

Two-dimensional long-axis echocardiographic views from right parasternal position. Each diagram on the left indicates the location of the ultrasound beam as it transects the heart from the right side, resulting in the corresponding echo image on the right. Long-axis four-chamber (left ventricular inflow) view is above. Long-axis view of the left ventricular outflow region is below. AO, Aorta; CH, chordae tendinae; LA, left atrium; LC, left coronary cusp of aortic valve; LV, left ventricle; LVW, left ventricular wall; MV, mitral valve; PM, papillary muscle; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; TV, tricuspid valve; VS, interventricular septum. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

# M-MODE ECHOCARDIOGRAPHY

This modality provides a one-dimensional view (depth) into the heart. M-mode images represent echos from various tissue interfaces along the axis of the beam (displayed vertically on the screen). These echos, which move during the cardiac cycle, are displayed against time (on the horizontal axis). Thus the "wavy" lines that are seen on these recordings correspond to the positions of particular structures in relation to the transducer as well as to each other at any point in time. Accurate placement of the M-mode beam using a moveable cursor line superimposed on an appropriate 2-D (real-time) image is important. M-mode images usually provide cleaner resolution of cardiac borders than 2-D because of higher sampling rate. Measurements of cardiac dimensions and motion throughout the cardiac cycle are often more accurately obtained from M-mode tracings,

#### 4-chamber (inflow) view

5-chamber (LV outflow) view

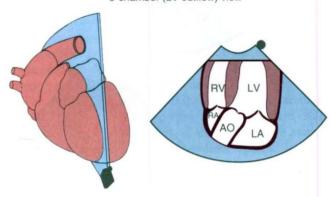

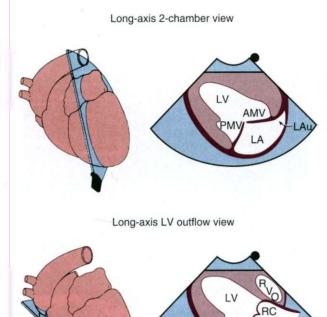

FIG 2-22

Left caudal (apical) parasternal position. Four-chamber view optimized for ventricular inflow is above. Five-chamber view optimized for left ventricular outflow is below. These views provide good Doppler velocity signals from mitral and aortic valve regions. AO, Aorta; AS, interatrial septum; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

especially when coupled with a simultaneously recorded ECG (or phonocardiogram). Difficulty in achieving consistent and accurate beam placement for standard measurements and calculations can be a limitation.

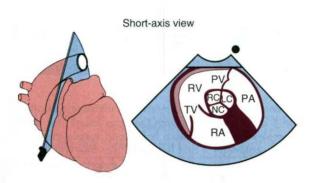

#### M-Mode Views

Standard M-mode views are obtained from the right parasternal transducer position. The M-mode cursor is positioned with 2-D guidance using the right parasternal short-axis view. Precise positioning of the ultrasound beam within the heart (perpendicular to the structures to be measured) and clear endocardial images are essential for accurate M-mode measurements and calculations. For example, papillary muscles within the left ventricle must be avoided when measuring free-wall thickness. Fig. 2-26 illustrates standard M-mode views. In cases in which the M-mode cursor cannot be optimally aligned (e.g., in animals with focal or asymmetric hypertrophy), wall thickness measurements from 2-D images are preferred.

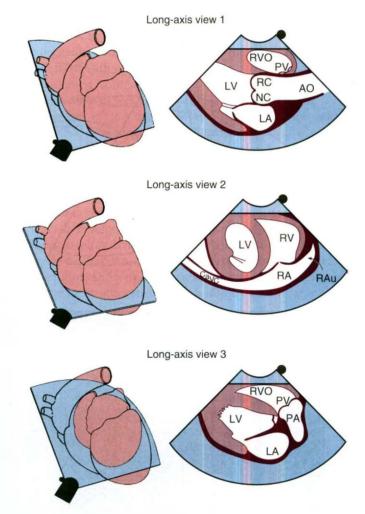

#### FIG 2-23

Left caudal (apical) parasternal 2-dimensional views optimized for left ventricular inflow and left auricle (above) and left ventricular outflow (below). AMV, Anterior (septal) mitral valve cusp; AO, aorta; LA, left atrium; LAu, left auricle; LV, left ventricle; PMV, posterior mitral valve cusp; RC, NC, right and noncoronary cusps of aortic valve; RVO, right ventricular outflow tract. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

#### FIG 2-24

Left cranial parasternal short-axis view optimized for right ventricular inflow and outflow. This view is useful for Doppler interrogation of tricuspid and pulmonary artery flows. PA, Pulmonary artery; PV, pulmonary valve; RA, right atrium; RC, LC, NC, right, left, and noncoronary cusps of aortic valve; RV, right ventricle; TV, tricuspid valve. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

#### FIG 2-25

Left cranial parasternal long-axis views optimized for aortic root (above), right atrium and auricle (middle), and right ventricular outflow and main pulmonary artery (below). These views are used to evaluate the heart base and can provide good Doppler signals for tricuspid and pulmonary flows. AO, Aorta; CaVC, caudal vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary valve; RA, right atrium; RAu, right auricle; RC, NC, right and noncoronary cusps of aortic valve; RV, right ventricle; RVO, right ventricular outflow tract. (From Thomas WP et al: Recommendations for standards in transthoracic 2-dimensional echocardiography in the dog and cat, J Vet Intern Med 7:247, 1993.)

# Common Measurements and Normal Values

The standard dimensions measured with M-mode and their timing are also indicated in Fig. 2-26. The leading edge technique is used when possible (i.e., from the edge closest to the transducer [leading edge] of one side of the dimension to the leading edge of the other). In this way, only one endocardial surface is included in the measurement. LV wall and interventricular septal thicknesses, as well as LV chamber dimensions, should be determined at the level of the chordae tendineae, rather than the apex or mitral valve level.

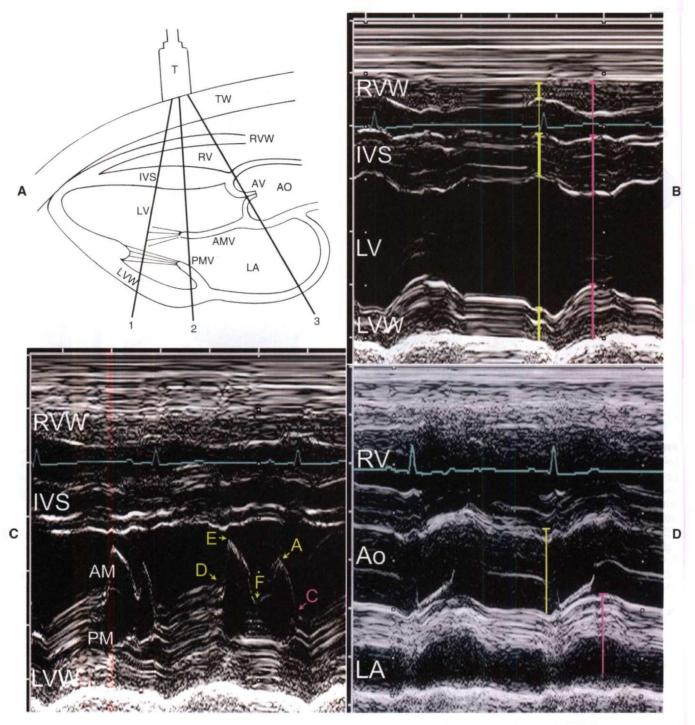

FIG 2-26

Common M-mode views. The diagram (A) indicates the approximate orientation of the one-dimensional ultrasound beam through the heart to achieve the corresponding M-mode images. A lead II ECG is recorded with the echo images for timing within the cardiac cycle. End diastole occurs at the onset of the QRS complex (yellow measure lines); end systole (pink measure lines) is the time when the dimension between the interventricular septum (IVS) and left ventricular free wall (LVW) is smallest. B, Image at the level of the chordae tendineae within the left ventricular lumen (LV), corresponding to cursor line "1" in A. Internal dimensions of the LV are measured from the leading (anterior) edge of the left endocardial wall of the IVS to the leading edge (luminal surface) of the posterior LVW. The thickness of the IVS is measured from the right endocardial surface of the IVS to the leading edge of the left endocardial septal wall at end diastole and end systole; the posterior LVW is measured at the same times from the endocardial surface to (but not including) the leading edge of the epicardial echoes. C, Image at the mitral valve level, cursor line "2" in A. The motion of the anterior (AM) and posterior (PM) mitral leaflets is described by the letters shown. Diastolic opening of the valve occurs at point D and systolic closing occurs at point C (see text for more information). D, Image at the aortic root (Ao) level "3" (where valve cusps are seen). Diameter is measured at end diastole from the leading (anterior) edge of the anterior aortic wall to the leading edge of the posterior wall. The left atrium (LA; usually the auricular region) is measured at the time of peak anterior aortic movement. RV, Right ventricular lumen; RVW, right ventricular wall.

Measurements may also be taken from 2-D images if they are of high resolution and frames from the appropriate times in the cardiac cycle are used. Somatotype, breed, and body size greatly influence echo measurements in dogs. Endurance training also affects measured parameters, reflecting the increased cardiac mass and volume associated with frequent and sustained strenuous exercise. Some guidelines for approximate normal canine values are found in Table 2-3. Normal measurements in cats are more uniform but are also influenced by body size (Table 2-4). Chamber volume and ejection fraction are better estimated from optimized 2-D frames using the modified Simpsons' method rather than M-mode images because of greater potential for inaccurate geometric assumptions from one dimensional measurements (see Supplemental Readings for further information). The right parasternal long axis view is usually better for assessing LV size than the left apical view.

Diastolic measurements are made at the onset of the QRS complex of a simultaneously recorded ECG. Systolic measurements of the LV are made from the point of peak downward motion of the septum to the leading edge of the LV free-wall endocardium at the same instant. The septum and LV wall normally move toward each other in systole, although their peak movement may not coincide if electrical activation is not simultaneous. Paradoxic septal motion, in which the septum seems to move away from the LV wall and toward the transducer in systole, occurs in some cases of RV volume and/or pressure overload. This abnormal septal motion can also be visualized on 2-D images; it precludes accurate assessment of LV function using fractional shortening.

The fractional shortening (FS; % delta D) is commonly used to estimate LV function. FS is the percent change in LV dimension from diastole to systole ([LVIDd – LVIDs]/LVIDd × 100). Most normal dogs have an FS between 25% to 27% and 40%; in most cats FS is 35% to 65%, although there is some variability. It is important to note that this index, like others taken during cardiac ejection, has the significant limitation of being dependent on ventricular loading conditions. For example, reduced LV afterload (as occurs from mitral insufficiency, ventricular septal defect, or peripheral vasodilation) facilitates ejection of blood and permits greater

FS, although intrinsic myocardial contractility is not increased. The exaggerated FS in patients with severe mitral regurgitation causes the appearance of increased contractility in those with normal myocardial function and can mask deteriorating contractile function. Regional wall motion abnormalities as well as arrhythmias can affect the FS.

The use of the calculated end-systolic volume index (ESVI) has been suggested as a more accurate way to assess myocardial contractility in the presence of mitral regurgitation. This index (ESV/m² body surface area) compares ventricular size after ejection with body size rather than with the volume-overloaded end-diastolic ventricular size. LV volume estimation from 2-D rather than M-mode images is recommended. Extrapolation from human studies suggests an ESVI <30 ml/m² is normal, 30 to 60 ml/m² indicates mild LV systolic dysfunction, 60 to 90 ml/m² represents moderate LV dysfunction, and >90 ml/m² indicates severe LV dysfunction. A number of other methods can also be used to assess LV function.

Mitral valve motion is also evaluated with M-mode. The anterior (septal) leaflet is most prominent and has an "M" configuration. The posterior (parietal) leaflet is smaller; its motion mirrors the anterior leaflet, appearing as a "W." Tricuspid valve motion is similar. The mitral valve motion pattern is identified by letters (see Figure 2-26). Point E occurs at maximal opening of the valve during the rapid ventricular filling phase. The valve drifts into a more closed position (point F) at the end of rapid ventricular filling. Atrial contraction causes the valve to open again (point A). At rapid heart rates the E and A points can merge. The mitral valve closes (point C) at the onset of ventricular systole. In normal animals the mitral E point is close to the interventricular septum. Increased E point-to-septal separation is usually associated with reduced myocardial contractility, but aortic insufficiency can also cause this. In animals with IV outflow obstruction, hemodynamic forces during ejection can pull the anterior mitral leaflet toward the septum. This is called systolic anterior motion (SAM), and it causes the normally straight mitral echos (between points C and D) to bend toward the septum during systole (see Figure 8-4). Diastolic flutter of the anterior mitral leaflet can sometimes

<sup>\*</sup>These values are based on the author's experience and compilation of published studies. Ketamine increases heart rate and decreases LVID<sub>d</sub>. See Suggested Readings for additional references.

<sup>†</sup>Orientation of M-mode cursor across the LA is variable among animals; maximal LA dimension is best assessed by 2-D imaging.

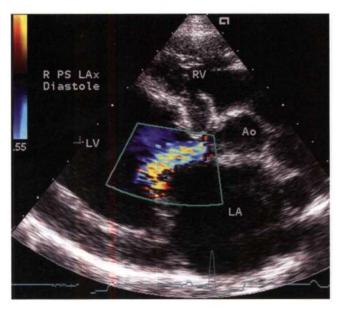

FIG 2-27

Color flow Doppler image of an aortic regurgitation jet angled toward and along the anterior leaflet of the mitral valve in a 2-year-old Rottweiler with aortic valve endocarditis. The regurgitant jet causes the mitral leaflet to flutter in diastole as seen in Fig. 2-28. Imaged from the right parasternal long axis position. Ao, Aorta; LA, left atrium; LV, left ventricle; RV, right ventricle.

be seen when an aortic insufficiency jet causes the leaflet to vibrate (Figures 2-27 and 2-28).

The diameter of the aortic root and sometimes its motion are measured with M-mode. The parallel walls of the aortic root shift rightward in systole. During diastole one or two aortic valve cusps may be seen as a straight line parallel to and centered between the aortic wall echoes. At the onset of ejection, the cusps separate toward the walls of the aortic root and then come together again at the end of ejection. The shape of these echoes (two cusps) has been described as a train of boxcars or little rectangular boxes attached together by a string. Aortic diameter is measured at end diastole. The amplitude of posterior-to-anterior motion of the aortic root is often decreased in animals with poor cardiac output. The LA dimension (behind the aortic root) is measured at maximal systolic excursion. In normal cats and dogs, the (M-mode) ratio of LA to aortic root diameters is about 1 to 1. However, LA size is underestimated with this M-mode view because (especially in dogs) the M-mode cursor usually transects the LA close to the left auricle, not at its maximal dimension. In cats the M-mode beam is more likely to cross the body of the LA, but its orientation can be inconsistent. Echo beam placement may be difficult in some animals, and the pulmonary artery can be inadvertently imaged instead. Therefore LA size assessment is best done from 2-D images.

Systolic time intervals (STIs) have been used sporadically to estimate cardiac function, but they are influenced by cardiac filling and afterload. These intervals can be calculated if the opening and closing of the aortic valve are clearly seen on M-mode and a simultaneous ECG is recorded for timing. The STIs are left ventricular ejection time (duration of time the aortic valve is open), preejection period (time from the onset of the QRS to aortic valve opening), and total electromechanical systole (left ventricular ejection time plus preejection period). STIs can also be derived with Doppler echocardiography.

# **CONTRAST ECHOCARDIOGRAPHY**

This technique, often called a "bubble study," uses rapid injection of a substance containing "microbubbles" either into a peripheral vein or selectively into the heart. These microbubbles generate tiny pinpoint echos that temporarily opacify the blood pool being imaged (Fig. 2-29). The microbubbles appear as bright sparkles moving with the blood flow. Agitated saline solution, a mixture of saline and the patient's blood, and other substances can be used as echocontrast material. Injection into a peripheral vein opacifies the right heart chambers; bubbles seen in the left heart or aorta indicate a right-to-left shunt. Saline microbubbles do not pass through the pulmonary capillaries (although some commercially available echo-contrast agents do), so echocontrast injection via selective left-sided heart catheterization is required to visualize intracardiac left-to-right shunts or mitral regurgitation. Doppler echocardiography has largely replaced echocontrast studies, but they are still a useful tool in some cases.

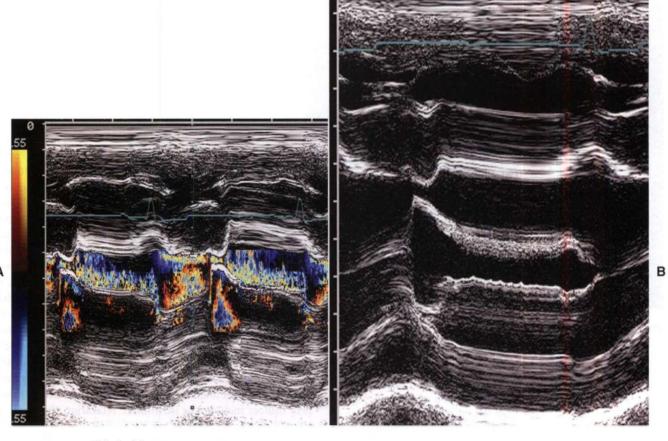

# DOPPLER ECHOCARDIOGRAPHY

Blood flow direction and velocity are imaged with Doppler echocardiography. Several types of Doppler echocardiography are used clinically: pulsed-wave (PW), continuous-wave (CW), and color flow (CF) mapping. Important clinical applications relate to identifying abnormal flow direction or turbulence and increased flow velocity. This allows detection and quantification of valvular insufficiency, obstructive lesions, and cardiac shunts. Cardiac output and other indicators of systolic function can be assessed, and there is much interest in Doppler-derived indices of diastolic function in patients with cardiac disease (see Suggested Readings). Adequate Doppler examinations are technically demanding. They are often very time consuming and require a good understanding of hemodynamic principles and cardiac anatomy.

The Doppler modality is based on detecting frequency shifts between the emitted ultrasound energy and echoes reflected from moving blood cells (the Doppler shift\*). Echoes returning from cells moving away from the transducer are of lower frequency, and those from cells moving toward the transducer are of higher frequency. The higher

<sup>\*</sup> $V = C(\pm \Delta f/2f_0\cos\theta)$ 

V, calculated blood flow velocity (meters/sec); C, speed of sound in soft tissue (1540 meters/sec);  $\pm$   $\Delta f$ , Doppler frequency shift;  $f_0$ , transmitted frequency;  $\theta$ , intercept angle (between ultrasound beam and blood flow direction).

Color M-mode (A) and standard M-mode (B) images of the mitral valve from the dog in Fig. 2-27. The disturbed flow from aortic regurgitation is seen as the colors along the anterior leaflet in the left ventricular outflow region. Fine fluttering of the anterior mitral leaflet is seen in B; the leaflet appears wide and "fuzzy" compared with the thin, discrete posterior leaflet.

the velocity of the cells, the greater the frequency shift. Optimal blood flow profiles and calculation of maximal blood flow velocity are possible when the ultrasound beam is aligned parallel to the flow. This is in contrast to the perpendicular beam orientation needed for optimal M-mode and 2-D imaging. With Doppler, calculated blood flow velocity diminishes as the angle of incidence between ultrasound beam and direction of blood flow diverges from 0 degrees. This is because the calculated flow velocity is inversely related to the cosine of this angle (cosine 0 degrees = 1). As long as the angle between the ultrasound beam and path of blood flow is less than 20 degrees, maximal flow velocity can be estimated with reasonable accuracy. As this angle of incidence increases, the calculated velocity decreases. At an angle of 90 degrees, the calculated velocity is 0 (cosine 90 degrees = 0); therefore no flow signal is recorded when the ultrasound beam is perpendicular to blood flow. Flow signals are usually displayed with time on the x axis and velocity (scaled in m/sec) on the y axis. A zero baseline demarcates flow away from (below baseline) or toward (above baseline) the transducer. Higher velocities are displayed farther from baseline. Other flow characteristics (e.g., turbulence) also affect the Doppler spectral display.

# **Pulsed Wave Doppler**

Pulsed wave (PW) Doppler uses short bursts of ultrasound to analyze echoes returned from a specified area (designated the sample volume) along the Doppler cursor line. The advantage of PW Doppler is that blood flow velocity, direction, and spectral characteristics can be calculated from a specific location in the heart or blood vessel. The main disadvantage is that the maximum measurable velocity is limited. The pulse repetition frequency (time required to send, receive, and process returning echoes), as well as the transmitted frequency and the distance of the sample volume from the transducer determine the maximum measurable velocity (called the *Nyquist limit*). The Nyquist limit is defined by two times the pulse repetition frequency. Lower frequency transducers and closer sample volume placement increase the Nyquist limit. When blood flow velocity is

FIG 2-29

Echo "bubble" study in a dog with pulmonary hypertension. Bright speckles fill the RA and RV chambers after an injection of agitated saline into a peripheral vein. Because there was no intracardiac shunt in this dog, no "bubbles" are seen in the left heart chambers, despite abnormally high right heart pressures. View from left apical position; Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

higher than the Nyquist limit, "aliasing" or velocity ambiguity occurs. This is displayed as a band of velocity signals extending above and below ("wrapped around") the baseline, so neither velocity nor direction is measurable (Fig. 2-30). The velocity spectrum displayed with PW Doppler when blood cells in the sample volume are moving in the same direction and at the same velocity is relatively thin (tight). Variation in velocity causes spectral broadening (widening).

Characteristic blood flow patterns are obtained from the different valve areas. Flow across both AV valves has a similar pattern; likewise, flow patterns across the semilunar valve areas are similar. Normal diastolic flow across the mitral valve (Fig. 2-31) and tricuspid valve consists of an initial higher velocity signal during the rapid ventricular filling phase (E wave), which is followed by a smaller velocity signal associated with atrial contraction (A wave). Breed, age, and body weight appear to have little influence on normal Doppler measurements. Peak velocities are normally higher across the mitral (peak E usually 0.9 to 1.0 m/sec; peak A usually 0.6 to 0.7 m/sec) compared with the tricuspid valve (peak E usually 0.8 to 0.9 m/sec; peak A usually 0.5 to 0.6 m/sec). The four-chamber left apical view usually provides optimal alignment for assessing mitral inflow velocities; the left cranial short axis view is usually best for tricuspid inflow, although several other imaging planes may provide adequate alignment. Doppler-derived diastolic function indices include the isovolumic relaxation time, mitral valve E/A ratio, and others.

Flow across the pulmonary and aortic valves (Fig. 2-32) accelerates rapidly during ejection, with more gradual decel-

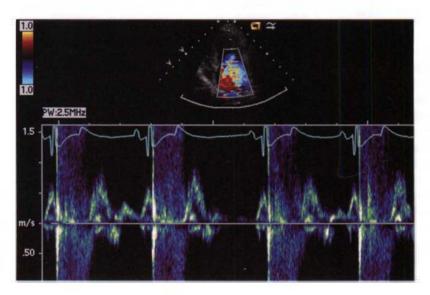

FIG 2-30

Mitral diastolic inflow and systolic regurgitant flow in a dog with degenerative mitral valve disease recorded with PW Doppler from left caudal parasternal position. The direction of mitral regurgitant flow is away from the transducer (below baseline); however, this direction cannot be discerned with PW because the flow velocity is too high. The signal is instead "wrapped around" the baseline (aliased).

FIG 2-31

Normal mitral valve inflow recorded with PW Doppler from left caudal parasternal position in a dog. The flow signal (above baseline) following the QRS-T of the ECG represents early diastolic flow into the ventricle (E); the second, smaller peak after the P wave represents inflow from atrial contraction (A). Velocity scale in meters/second is on the left.

eration. Peak systolic pulmonary velocity is 1.4 to 1.5 m/sec in most normal dogs. The left cranial views usually provide better flow alignment. Sample volume placement is at or just distal to the valve. Peak aortic velocity is usually <1.6 to 1.7 m/sec, although some normal dogs have peak aortic velocities above 2 m/sec related to increased stroke volume or high sympathetic tone, especially if unsedated. Ventricular outflow obstruction causes more rapid flow acceleration, increased peak velocity, and turbulence. In general, aortic velocities over 2.2 (-2.4) m/sec are suggestive of outflow obstruction. Between 1.7 and ~2.2 m/sec lies a "grey zone" where mild LV outflow obstruction (e.g., some cases of subaortic stenosis) cannot be differentiated with certainty from normal but vigorous left ventricular ejection. Maximal aortic/LV outflow velocities are obtained in most dogs from the subcostal (subxiphoid) position; however, in some dogs the left apical view provides higher velocity recordings. The LV outflow region should be interrogated from both views and the greater maximal velocity value used.

# **Continuous Wave Doppler**

Continuous wave (CW) Doppler employs continuous and simultaneous ultrasound transmission and reception along the line of interrogation. Theoretically, there is no maximum velocity limit with CW Doppler, so high-velocity flows can be measured (Fig. 2-33). The disadvantage of CW Doppler is that sampling of blood flow velocity and direction occurs all along the ultrasound beam, not in a specified area (so-called range ambiguity).

# **Pressure Gradient Estimation**

Doppler estimation of pressure gradients is used in combination with M-mode and 2-D imaging to assess the severity of congenital or acquired flow obstructions. In addition, regurgitant jet maximal velocity estimates the peak pressure gradient across the regurgitant valve. The instantaneous pressure gradient across a stenotic or regurgitant valve is estimated using the maximal measured velocity of the flow jet. CF Doppler is useful to depict jet orientation. Careful Doppler beam alignment is essential in order to measure maximum velocity. CW Doppler is employed if aliasing occurs with PW Doppler. A modification of the Bernoulli equation is used to estimate pressure gradient:

# Pressure gradient = $4(\text{maximum velocity})^2$

Other factors involved in this relationship are usually of minimal clinical importance and are generally ignored.

Pulmonary arterial systolic pressure can be estimated (if there is no pulmonic stenosis) by using the maximal tricuspid regurgitation jet velocity (TRmax). The calculated systolic pressure gradient plus about 8 to 10 mm Hg (or the measured central venous pressure) equals the peak right ventricular systolic pressure, which approximates pulmonary artery systolic pressure. Pulmonary hypertension (PH) is associated when TRmax exceeds 2.8 m/s. The severity of PH is often categorized as mild (~35-50 mm Hg; TRmax 2.9-3.5 m/s), moderate (~51-75 mm Hg; TRmax 3.6-4.3 m/s), or severe (>75 mm Hg; TRmax >4.3 m/s). Likewise, pulmonary diastolic pressure can be estimated from pulmonary

Normal pulmonary flow recorded with PW Doppler from left cranial short-axis position in a dog. There is rapid blood acceleration (below baseline) into the pulmonary artery, with a peak velocity of about 1.0 m/sec. Velocity scale in meters per second is on the left.

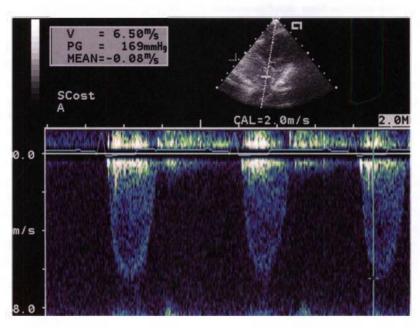

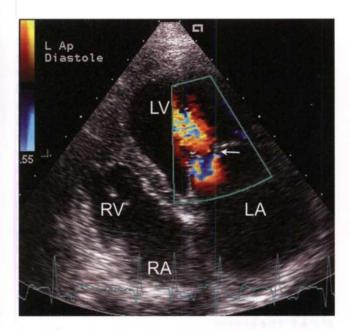

FIG 2-33
CW Doppler recording of high-velocity aortic outflow in a dog with severe subaortic stenosis, imaged from the subcostal position. Estimated systolic pressure gradient across the outflow region is 169 mm Hg based on a peak velocity of 6.5 m/sec. Velocity scale in meters/second is on the left.

regurgitant (PR) jet velocity at end-diastole. The calculated end-diastolic pressure gradient between the pulmonary artery and the right ventricle, plus the estimated right ventricular diastolic pressure, represents pulmonary arterial diastolic pressure. Pulmonary hypertension is also suggested by a peak PR velocity of >2.2 m/s.

## **Color Flow Mapping**

Color flow (CF) mapping is a form of PW Doppler that combines the M-mode or 2-D modality with blood flow imaging. However, instead of one sample volume along one scan line, many sample volumes are analyzed along multiple scan lines. The mean frequency shifts obtained

Nyquist limit, causing red-coded flow (blood moving toward transducer) to alias to blue, then again to red, and once more to blue. Turbulent flow is seen within the left ventricle at the top of the 2-D image.

from multiple sample volumes are color-coded for direction (in relation to the transducer) and velocity. Most systems code blood flow toward the transducer as red and blood flow away from the transducer as blue. Zero velocity is indicated by black, meaning either no flow or flow that is perpendicular to the angle of incidence. Differences in relative velocity of flow can be accentuated, and the presence of multiple velocities and directions of flow (turbulence) can be indicated by different display maps that use variations in brightness and color. Aliasing occurs often, even with normal blood flows, because of low Nyquist limits. Signal aliasing is displayed as a reversal of color (e.g., red shifting to blue; Fig. 2-34). Turbulence produces multiple velocities and directions of flow in an area, resulting in a mixing of color; this display can be enhanced using a variance map, which adds shades of yellow or green to the red/blue display (Fig. 2-35).

The severity of valve regurgitation is sometimes estimated by the size and shape of the regurgitant jet during CF imaging. Although technical and hemodynamic factors confound the accuracy of such assessment, wide and long regurgitant jets are generally associated with more severe regurgitation than narrow jets. Other methods for quantifying valve regurgitation have been described as well. Maximum regurgitant jet velocity is not a good indicator of severity, especially with mitral regurgitation. Changes in chamber size provide a better indication of severity with chronic regurgitation.

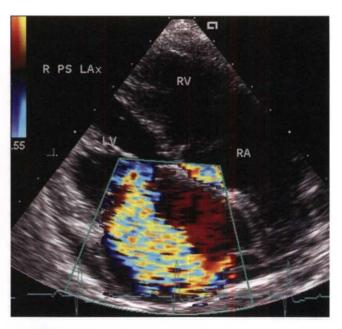

FIG 2-35
Systolic frame showing turbulent regurgitant flow into the enlarged LA of a dog with chronic mitral valve disease. The regurgitant jet curves around the dorsal aspect of the LA. Imaged from the right parasternal long axis, four chamber view. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

## **Doppler Tissue Imaging**

Doppler tissue imaging (DTI) is a modality used to assess the motion of tissue, rather than blood cells, by altering the signal processing and filtering of returning echoes. Myocardial velocity patterns can be assessed with color flow and pulsed wave spectral DTI techniques. Spectral DTI provides greater temporal resolution and quantifies velocity of myocardial motion at specific locations, such as the lateral or septal aspects of the mitral annulus (Fig. 2-36). Color DTI methods display mean myocardial velocities from different regions. Other techniques used to assess regional myocardial function and synchrony are derived from DTI methods; these include myocardial velocity gradients, myocardial strain, strain rate, and velocity vector imaging.

# TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) uses specialized transducers mounted on a flexible, steerable endoscope tip to image cardiac structures through the esophageal wall. TEE can provide clearer images of some cardiac structures (especially those at or above the AV junction) compared with transthoracic echocardiography because chest wall and lung interference is avoided. This technique can be particularly useful for defining some congenital cardiac defects and identifying thrombi, tumors, or endocarditis lesions, as well as guiding cardiac interventional procedures (Fig. 2-37). The need for general anesthesia and the expense of the

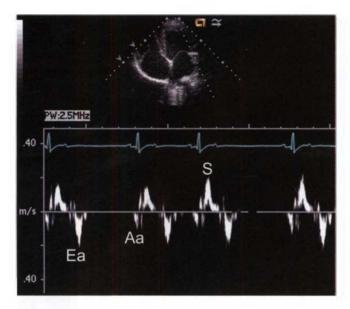

FIG 2-36

PW Doppler tissue image from a cat. The mitral annulus moves toward the left apex (and transducer) in systole (S). Early diastolic filling (Ea) shifts the annulus away from the apex as the LV expands. Additional motion occurs with late diastolic filling from atrial contraction (Aa).

endoscopic transducers are the main disadvantages of TEE. Complications related to the endoscopy procedure appear to be minimal.

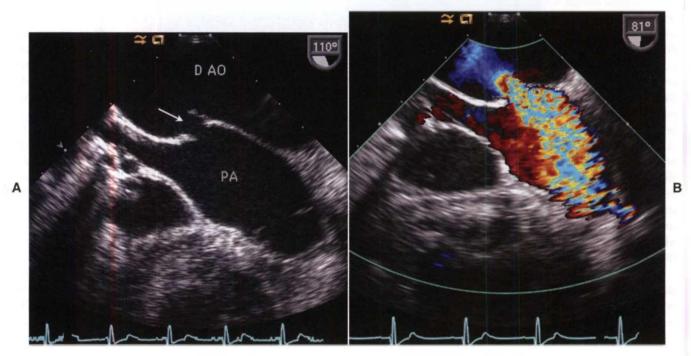

## THREE-DIMENSIONAL **ECHOCARDIOGRAPHY**

The ability to generate and manipulate 3-dimensional (3-D) images of the heart and other structures is a promising new way to evaluate cardiac structure and function. Anatomic and blood flow abnormalities can be viewed from any angle by rotating or bisecting the 3-D images. Current technology requires several cardiac cycles in order to acquire sufficient data for 3-D reconstruction of the entire heart, although true "real time" 3-D echocardiography will soon be available.

## OTHER TECHNIQUES

## **CENTRAL VENOUS PRESSURE MEASUREMENT**

Central venous pressure (CVP) is influenced by intravascular volume, venous compliance, and cardiac function. CVP measurement helps in differentiating high right heart filling pressure (as from right heart failure or pericardial disease) from other causes of pleural or peritoneal effusion. But it is important to note that pleural effusion itself can increase intrapleural pressure enough to impair cardiac filling; this

A, Two-dimensional transesophageal echo (TEE) image at the heartbase from a 5-year-old English Springer Spaniel shows a patent ductus arteriosus (arrow) between the descending aorta (D Ao) and pulmonary artery (PA). B, Color flow Doppler image in diastole from the same orientation demonstrates flow acceleration toward the ductal opening in the D Ao and the turbulent ductal flow into the PA.

can raise CVP even in the absence of cardiac discase. Therefore CVP should be measured after thoracocentesis in patients with moderate- to large-volume pleural effusion. CVP is sometimes used to monitor critical patients receiving large intravenous fluid infusions. However, CVP is not an accurate reflection of left heart filling pressure and thus is not a reliable way to monitor for cardiogenic pulmonary edema. The CVP in normal dogs and cats usually ranges from 0 to 8 (up to 10) cm H<sub>2</sub>O. Fluctuations in CVP that parallel those of intrapleural pressure occur during respiration.

CVP is measured via a large-bore jugular catheter that extends into or close to the right atrium. The catheter is placed aseptically and connected by extension tubing and a three-way stopcock to a fluid administration set. A water manometer is attached to the stopcock and positioned vertically, with the stopcock (representing 0 cm H2O) placed at the same horizontal level as the patient's right atrium. The stopcock is turned off to the animal, allowing the manometer to fill with crystalloid fluid; then the stopcock is turned off to the fluid reservoir so that the fluid column in the manometer equilibrates with the animal's CVP. Repeated measurements are more consistent when taken with the animal and manometer in the same position and during the expiratory phase of respiration. Small fluctuations in the manometer's fluid meniscus occur with the heartbeat, and slightly larger movement is associated with respiration. Marked change in the height of the fluid column associated with the heartbeat suggests either severe tricuspid insufficiency or that the catheter tip is within the right ventricle.

## **BIOCHEMICAL MARKERS**

A number of specific biochemical markers are being evaluated for their diagnostic and prognostic potential. Cardiac troponins are more sensitive for detecting myocardial injury than cardiac-specific creatine kinase (CK-MB) and other biochemical markers of muscle damage. In dogs the CK-MB isoform comprises only a minority of total cardiac CK, and it is also present in noncardiac tissues. Cardiac troponins are regulatory proteins associated with cardiac actin (thin) contractile filaments. Circulating concentrations of cardiac troponin I (cTnI) and cardiac troponin T (cTnT) provide a specific indicator of myocardial injury or necrosis. The pattern and degree of their release can depend on the type and severity of myocyte injury. Although there is an association between acute injury and the degree of increase in serum troponin concentration, this relationship is less clear in patients with chronic disease. After acute myocyte damage, serum cTn concentration increases within a few hours, peaks in 12 to 24 hours, and then declines over the next few weeks. Myocardial inflammation, trauma, congestive heart failure, hypertrophic cardiomyopathy, and gastric dilatation/volvulus have been associated with increased cardiac toponin concentrations. In dogs with congestive heart failure or hypertrophic cardiomyopathy, this probably relates to continued myocardial remodeling, not just acute damage from myocardial infarction. cTnI appears to be more specific than cTnT. Human assays for cTnI and cTnT can be used in dogs and cats, but because methodology is not standardized among various cTnI assays, the cut-off values for normal may vary. Furthermore, cTn values that indicate clinically relevant myocardial disease or damage in animals are unclear.

The natriuretic peptides, ANP, BNP, and their precursors, are other potentially useful biomarkers for assessing the presence and possibly prognosis of heart failure. Circulating natriuretic peptide concentrations increase in association with vascular volume expansion and decreased renal clearance and when their production is stimulated (e.g., with ventricular strain and hypertrophy, hypoxia, or tachycardia). The natriuretic peptides should be used as functional markers of cardiac disease rather than of specific pathology. Issues of standardization among different commercial assays and methodologies and lack of universal reference values are limitations. The N-terminal fragments (NT-proANP and NT-proBNP) of the natriuretic peptide precursor molecules remain in circulation longer and reach higher plasma concentrations than the active hormone molecules. Because ANP and NT-proANP amino acid sequences are highly conserved among people, dogs, and cats, human assays may be used. Canine and feline BNP are similar, but differences from people preclude the use of most human BNP assays. Canine and feline NT-proBNP measurement is commercially available, although questions regarding interpretation of results remain. Plasma BNP and NT-proBNP are sensitive and specific markers for chronic LV dysfunction in people, and high concentrations are negatively correlated with prognosis. BNP as well as NT-proANP are high in most cats with hypertrophic cardiomyopathy. Elevated concentrations are also seen in dogs with heart disease and heart failure, but overlap in these concentrations compared with those of some dogs without heart disease is of concern. Studies are ongoing to clarify the potential usefulness of plasma natriuretic peptides in dogs with cardiac disease.

Other biomarkers are currently being evaluated. The endothelin (ET) system is activated in dogs and cats with heart failure and in those with pulmonary hypertension, so assays for plasma ET-like immunoreactivity may be useful. Tumor necrosis factor (TNF $_{\alpha}$ ) may also be a useful marker of cardiac disease progression, but it is not cardiac specific.

### **ANGIOCARDIOGRAPHY**

Nonselective angiocardiography can be used to diagnose several acquired and congenital diseases, including cardiomyopathy and heartworm disease in cats, severe pulmonic or (sub)aortic stenosis, patent ductus arteriosus, and tetralogy of Fallot. Intracardiac septal defects and valvular regurgitation cannot be reliably identified. The quality of such studies is higher with rapid injection of radiopaque agents via a large-bore catheter and with smaller patient size. In most cases, echocardiography provides similar information more safely. However, evaluation of the pulmonary vasculature is better accomplished using nonselective angiocardiography.

Selective angiocardiography is performed by advancing cardiac catheters into specific areas of the heart or great vessels. Injection of contrast material is generally preceded by the measurement of pressures and oxygen saturations. This technique allows identification of anatomic abnormalities and the path of blood flow. Doppler echocardiography may provide comparable diagnostic information noninvasively. However, selective angiography is a necessary component of many cardiac interventional procedures.

## CARDIAC CATHETERIZATION

Cardiac catheterization allows measurement of pressure, cardiac output, and blood oxygen concentration from specific intracardiac locations. Specialized catheters are selectively placed into different areas of the heart and vasculature via the jugular vein, carotid artery, or the femoral vessels. Congenital and acquired cardiac abnormalities can be identified and assessed with these procedures in combination with selective angiocardiography. The advantages of Doppler echocardiography often outweigh those of cardiac catheterization, especially in view of the good correlation between certain Doppler- and catheterization-derived measurements. However, cardiac catheterization is necessary for balloon valvuloplasty, ductal occlusion, and other interventional procedures.

Pulmonary capillary wedge pressure (PCWP) monitoring is sometimes performed in dogs with heart failure because it provides an estimate of left heart filling pressure (in the absence of left ventricular inflow obstruction). To obtain PCWP, an end-hole, balloon-tipped (Swan-Ganz) catheter is passed into the main pulmonary artery. When the balloon is inflated and the catheter allowed to become wedged in a smaller pulmonary artery, flow in that vessel is occluded. The pressure measured at the catheter tip reflects pulmonary capillary pressure, which essentially is equivalent to left atrial pressure. This invasive technique allows differentiation of cardiogenic from noncardiogenic pulmonary edema and provides a means of monitoring the effectiveness of heart failure therapy. However, its use requires meticulous, aseptic catheter placement and continuous patient monitoring.

# OTHER NONINVASIVE IMAGING Nuclear Cardiology

Radionuclide, or nuclear, methods of evaluating cardiac function are available at some veterinary referral centers. These techniques can provide noninvasive assessment of cardiac output, ejection fraction, and other measures of cardiac performance as well as myocardial blood flow and metabolism.

## Cardiac Computed Tomography and Magnetic Resonance Imaging

Cardiac computed tomography and magnetic resonance imaging are available in some centers. These techniques depict greater contrast between cardiovascular structures and the blood pool as well as differentiate certain types of tissue. Because cardiac movement during the imaging sequence reduces image quality, some type of physiologic (ECG) gating, as well as rapid image acquisition, are needed. Identification of pathologic morphology is a major application, although myocardial function, perfusion, and blood flow studies may be done depending on the technical capability of the equipment. Novel MR techniques also allow noninvasive evaluation of blood vessels, including calculation of peripheral resistance.

#### **PNEUMOPERICARDIOGRAPHY**

Pneumopericardiography may be helpful in delineating the cause of pericardial effusions, especially if echocardiography is unavailable. This technique and pericardiocentesis are described in Chapter 9.

### **ENDOMYOCARDIAL BIOPSY**

Small samples of endocardium and adjacent myocardium can be obtained using a special bioptome passed into the right ventricle via a jugular vein. Routine histopathology and other techniques to evaluate myocardial metabolic abnormalities can be performed on the biopsy samples. Endomyocardial biopsy is most often used for myocardial disease research and is not commonly used in clinical veterinary cardiology.

Strategies for Refractory Congestive Heart Failure

## OVERVIEW OF HEART FAILURE

Heart failure entails abnormalities of cardiac systolic or diastolic function, or both. These can occur without evidence of abnormal fluid accumulation (congestion), especially in the initial stages of disease. Congestive heart failure (CHF) is characterized by high cardiac filling pressure, which leads to venous congestion and tissue fluid accumulation. It is a complex clinical syndrome rather than a specific etiologic diagnosis. The pathophysiology of heart failure is complex. It involves structural and functional changes within the heart and vasculature as well as other organs. The process of progressive cardiac remodeling inherent to heart failure can develop secondary to cardiac injury or stress from valvular

disease, genetic mutations, acute inflammation, ischemia, increased systolic pressure load, and other causes.

#### CARDIAC RESPONSES

Cardiac remodeling refers to the changes in myocardial size, shape, and stiffness that occur in response to various mechanical, biochemical, and molecular signals induced by the underlying injury or stress. These changes include myocardial cell hypertrophy, cardiac cell drop-out or selfdestruction (apoptosis), excessive interstitial matrix formation, fibrosis, and destruction of normal collagen binding between individual myocytes. The latter, resulting from effects of myocardial collagenases or matrix metalloproteinases, can cause dilation or distortion of the ventricle from myocyte slippage. Stimuli for remodeling include mechanical forces (e.g., increased wall stress from volume or pressure overload) and also various neurohormones (e.g., angiotensin II, norepinephrine, endothelin, aldosterone) and cytokines (e.g., tumor necrosis factor [TNF]-alpha). Contributing biochemical abnormalities related to cellular energy production, calcium fluxes, protein synthesis, and catecholamine metabolism have been variably identified in different models of heart failure and in clinical patients. Myocyte hypertrophy and reactive fibrosis increase total cardiac mass by eccentric and, in some cases, concentric patterns of hypertrophy. Ventricular hypertrophy can increase chamber stiffness, impair relaxation, and increase filling pressures; these abnormalities of diastolic function can also contribute to systolic failure. Ventricular remodeling also promotes the development of arrhythmias. The initiating stimulus underlying chronic cardiac remodeling may occur years before clinical evidence of heart failure appears.

Acute increases in ventricular filling (preload) induce greater contraction force and blood ejection. This response, known as the Frank-Starling mechanism, allows beat-to-beat adjustments that balance the output of the two ventricles and increase overall cardiac output in response to acute increases in hemodynamic load. The Frank-Starling effect helps normalize cardiac output under conditions of increased pressure and/or volume loading, but these conditions also increase ventricular wall stress and oxygen consumption.

Ventricular wall stress is directly related to ventricular pressure and internal dimensions and inversely related to wall thickness (Laplace's law). Myocardial hypertrophy can reduce wall stress. The pattern of hypertrophy that develops depends on the underlying disease. A ventricular systolic pressure load induces "concentric" hypertrophy; myocardial fibers and ventricular walls thicken as contractile units are added in parallel. A volume load causes "eccentric" hypertrophy; myocardial fiber elongation and chamber dilation occur as new sarcomeres are laid down in series. Compensatory hypertrophy lessens the importance of the Frank-Starling mechanism in stable, chronic heart failure. Although volume loads are better tolerated because myocardial oxygen demand is not as severe, both abnormal pressure and volume loading impair cardiac performance over time. Eventually, decompensation and myocardial failure develop. In patients with primary myocardial diseases, initial cardiac pressure and volume loads are normal, but intrinsic defects of the heart muscle lead to the hypertrophy and dilation observed.

Cardiac hypertrophy and other remodeling begin long before heart failure becomes manifest. In addition to myocyte hypertrophy, cardiac remodeling can include cell loss or self-destruction (apoptosis), excessive interstitial matrix formation, and loss of normal collagen binding. Myocyte hypertrophy and reactive fibrosis increase total cardiac mass as well as ventricular stiffness. This promotes elevated filling pressures and predisposes the patient to ischemia. Increased chamber size increases wall stress and myocardial O<sub>2</sub> demand. Biochemical abnormalities involving cell energy production, calcium fluxes, and contractile protein function can develop. Clinical heart failure can be considered a state of decompensated hypertrophy; ventricular function progressively deteriorates as contractility and relaxation become more deranged.

Continued exposure to increased sympathetic stimulation reduces cardiac sensitivity to catecholamines. Downregulation (reduced number) of myocardial  $\beta_1$ -receptors and other changes in cellular signaling may help protect the myocardium against the cardiotoxic and arrhythmogenic effects of catecholamines. Beta-blocking agents can reverse  $\beta_1$ -receptor down-regulation but may worsen heart failure. Cardiac  $\beta_2$ - and  $\alpha_1$ -receptors are also present but are not down-regulated; these are thought to contribute to myocardial remodeling and arrhythmogenesis. Another cardiac receptor subtype ( $\beta_3$ -receptors) may promote myocardial function deterioration through a negative inotropic effect.

# SYSTEMIC RESPONSES Neurohormonal Mechanisms

Neurohormonal (NH) responses contribute to cardiac remodeling and also have more far-reaching effects. Over time, excessive activation of neurohormonal "compensatory" mechanisms leads to the clinical syndrome of CHF. Although these mechanisms support circulation in the face of acute hypotension and hypovolemia, their chronic activation accelerates further deterioration of cardiac function. Major neurohormonal changes in heart failure include increases in sympathetic nervous tone, attenuated vagal tone,

activation of the renin-angiotensin-aldosterone system, and release of antidiuretic hormone (ADH-vasopressin). These neurohormonal systems work independently and together to increase vascular volume (by sodium and water retention and increased thirst) and vascular tone (Fig. 3-1). Excessive volume retention results in edema and effusions. Prolonged systemic vasoconstriction increases the workload on the heart, can reduce forward cardiac output, and may exacerbate valvular regurgitation. The extent to which these mechanisms are activated varies with the severity and etiology of heart failure. In general, as failure worsens, neurohormonal activation increases. Increased production of endothelins and proinflammatory cytokines, as well as altered expression of vasodilatory and natriuretic factors, also contribute to the complex interplay among these NH mechanisms and their consequences.

The effects of sympathetic stimulation (e.g., increased contractility, heart rate, and venous return) can increase cardiac output initially, but over time these effects become detrimental by increasing afterload stress and myocardial oxygen requirements, contributing to cellular damage and myocardial fibrosis, and enhancing the potential for cardiac arrhythmias. Normal feedback regulation of sympathetic nervous and hormonal systems depends on arterial and atrial baroreceptor function. Baroreceptor responsiveness becomes attenuated in chronic heart failure, which contributes to sustained sympathetic and hormonal activation and reduced inhibitory vagal effects. Baroreceptor function can improve with reversal of heart failure, increased myocardial contractility, decreased cardiac loading conditions, or inhibition of angiotensin II (which directly attenuates baroreceptor sensitivity). Digoxin has a positive effect on baroreceptor sensitivity.

The renin-angiotensin system has far-reaching effects. Whether systemic renin-angiotensin-aldosterone activation always occurs before overt congestive failure is unclear, and may depend on the underlying etiology. Renin release from the renal juxtaglomerular apparatus occurs secondary to low renal artery perfusion pressure, renal β-adrenergic receptor stimulation, and reduced Na+ delivery to the macula densa of the distal renal tubule. Stringent dietary salt restriction and diuretic or vasodilator therapy can promote renin release. Renin facilitates conversion of the precursor peptide angiotensinogen to angiotensin I (an inactive form). Angiotensin-converting enzyme (ACE), found in the lung and elsewhere, converts angiotensin I to the active angiotensin II and is involved in the degradation of certain vasodilator kinins. There are also other pathways that generate angiotensin II.

Angiotensin II has several important effects, including potent vasoconstriction and stimulation of aldosterone release from the adrenal cortex. Additional effects of angiotensin II include increased thirst and salt appetite, facilitation of neuronal norepinephrine synthesis and release, blockade of neuronal norepinephrine reuptake, stimulation of antidiuretic hormone (vasopressin) release, and increased adrenal epinephrine secretion. Inhibition of ACE can reduce

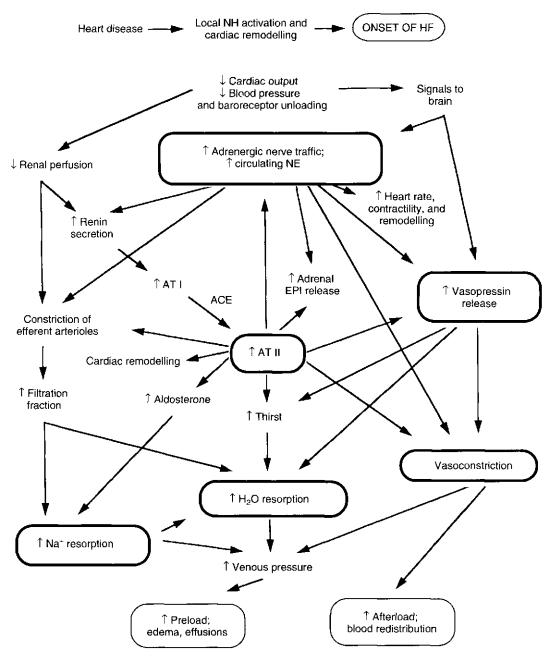

FIG 3-1
Major neurohormonal mechanisms leading to volume retention and increased afterload in congestive heart failure. ACE, Angiotensin-converting enzyme; AT, angiotensin; EPI, epinephrine; HF, heart failure; NE, norepinephrine.

NH activation and promote vasodilation and diuresis. Local production of angiotensin II also occurs in the heart, vasculature, adrenal glands, and other tissues. Local activity affects cardiovascular structure and function by enhancing sympathetic effects and promoting tissue remodeling that can include hypertrophy, inflammation, and fibrosis.

Aldosterone promotes sodium and chloride reabsorption as well as potassium and hydrogen ion secretion in the renal collecting tubules; the concurrent water reabsorption augments vascular volume. Increased aldosterone concentration can promote hypokalemia, hypomagnesemia, and impaired baroreceptor function. Aldosterone is also produced locally in the cardiovascular system and mediates inflammation and fibrosis. Chronic exposure can be detrimental to ventricular function and contribute to pathologic remodeling and myocardial fibrosis.

Antidiuretic hormone is released from the posterior pituitary gland. This hormone directly causes vasoconstriction and also promotes free water reabsorption in the distal nephrons. Although increased plasma osmolality or reduced blood volume are the normal stimuli for ADH release, reduced effective circulating volume and other nonosmotic stimuli

cause continued release of ADH in patients with heart failure. The continued release of ADH contributes to the dilutional hyponatremia sometimes found in patients with heart failure.

Increased circulating concentrations of other substances that play a role in abnormal myocardial hypertrophy and/or fibrosis, including cytokines (e.g.,  $TNF_{\alpha}$ ) and endothelins, have also been detected in animals with severe heart failure. Endothelin production is stimulated by hypoxia and vascular mechanical factors but also by angiotensin II, ADH, norepinephrine, cytokines (including  $TNF_{\alpha}$  and interleukin-I), and other factors.

Endogenous mechanisms that oppose the vasoconstrictor responses also are activated. These include natriuretic peptides, nitric oxide, and vasodilator prostaglandins. Normally, a balance between vasodilator and vasoconstrictor effects maintains circulatory homeostasis as well as renal solute excretion. As heart failure progresses, the influence of the vasoconstrictor mechanisms predominates despite increased activation of vasodilator mechanisms.

Natriuretic peptides are synthesized in the heart and play an important role in regulation of blood volume and pressure. Atrial natriuretic peptide (ANP) is synthesized by atrial myocytes as a prohormone, which is then cleaved to the active peptide after release stimulated by mechanical stretch of the atrial wall. Brain natriuretic peptide (BNP) is also synthesized in the heart, mainly by the ventricles in response to myocardial dysfunction or ischemia. Natriuretic peptides cause diuresis, natriuresis, and peripheral vasodilation. They act to antagonize the effects of the renin-angiotensin system and can also alter vascular permeability and inhibit growth of smooth muscle cells. Natriuretic peptides are degraded by neutral endopeptidases. Circulating concentrations of ANP and BNP increase in patients with heart failure. This increase has been correlated with pulmonary capillary wedge pressure and severity of heart failure in both dogs and people.

Nitric oxide (NO), produced in vascular endothelium in response to endothelial-nitric oxide synthetase (NOS), is a functional antagonist of endothelin and angiotensin II. This response is impaired in patients with heart failure. At the same time, myocardial inducible—NOS expression is enhanced; myocardial NO release has negative effects on myocyte function. Intrarenal vasodilator prostaglandins oppose the action of angiotensin II on the renal vasculature. The use of prostaglandin synthesis inhibitors in dogs or cats with severe heart failure could potentially reduce glomerular filtration (by increasing afferent arteriolar resistance) and enhance sodium retention.

## **Renal Effects**

Renal efferent glomerular arteriolar constriction, mediated by sympathetic stimulation and angiotensin II, helps maintain glomerular filtration in the face of reduced cardiac output and renal blood flow. Higher oncotic and lower hydrostatic pressures develop in the peritubular capillaries, enhancing the reabsorption of tubular fluid and sodium. Angiotensin II—mediated aldosterone release further promotes sodium and water retention. Continued activation of these mechanisms leads to clinical edema and effusions.

Afferent arteriolar vasodilation mediated by endogenous prostaglandins and natriuretic peptides can partially offset the effects of efferent vasoconstriction, but progressive impairment of renal blood flow leads to renal insufficiency. Diuretics not only can magnify azotemia and electrolyte loss but can further reduce cardiac output and activate the neurohormonal mechanisms.

## Other Effects

Reduced exercise capacity, along with skeletal muscle atrophy, occurs in patients with heart failure. Poor diastolic filling, inadequate forward output, and pulmonary edema or pleural effusion can interfere with exercise ability. Furthermore, impaired peripheral vasodilation during exercise contributes to inadequate skeletal muscle perfusion and fatigue. Excessive peripheral sympathetic tone, angiotensin II (both circulating and locally produced), and vasopressin can contribute to impaired skeletal muscle vasodilatory capacity in patients with CHF. Increased vascular wall sodium content and interstitial fluid pressure stiffen and compress vessels. Other mechanisms can include impaired endothelium-dependent relaxation, increased endothelin concentration, and vascular wall changes induced by the growth factor effects of various neurohormonal vasoconstrictors. ACE inhibitor therapy, with or without spironolactone, may improve endothelial vasomotor function and exercise capacity. Pulmonary endothelial function is improved by ACE inhibitors in dogs with CHE.

#### GENERAL CAUSES OF HEART FAILURE

The causes of heart failure are quite diverse; it can be useful to think of them in terms of underlying pathophysiology. In most cases of heart failure, the major initiating abnormality is myocardial (systolic pump) failure, systolic pressure overload, volume overload, or reduced ventricular compliance (impaired filling). Nevertheless, several pathophysiologic abnormalities often coexist; both systolic and diastolic function abnormalities are common in patients with advanced failure.

Myocardial failure is characterized by poor ventricular contractile function, and it is most commonly secondary to idiopathic dilated cardiomyopathy; valvular insufficiency may or may not be present initially but usually develops as the affected ventricle dilates. Persistent tachyarrhythmias, some nutritional deficiencies, and other cardiac insults also can lead to myocardial failure (see Chapters 7 and 8). Diseases that cause a volume or flow overload to the heart usually involve a primary "plumbing" problem (e.g., a leaky valve or abnormal systemic-to-pulmonary connection). Cardiac pump function is often maintained at a near-normal level for a prolonged time, but myocardial contractility does eventually deteriorate (see Chapters 5 and 6). Pressure overload results when the ventricle must generate higherthan-normal systolic pressure to eject blood. Concentric hypertrophy increases ventricular wall thickness and stiffness and predisposes the patient to ischemia. Excessive pressure loads eventually lead to a decline in myocardial contractility. Myocardial pressure overload results from congenital ventricular outflow obstruction and systemic or pulmonary hypertension (see Chapters 5, 10, and 11). Diseases that restrict ventricular filling impair diastolic function. These include hypertrophic and restrictive myocardial disease and pericardial disease (see Chapters 8 and 9). Contractile ability is usually normal initially, but high filling pressure leads to congestion behind the ventricle(s) and may diminish cardiac output. Examples of common diseases are listed in Table 3-1 according to their main initiating pathophysiology and typical clinical manifestation of CHF signs.

TABLE 3-1

Common Causes of Congestive Heart Failure (CHF)

Common Causes of Congestive Heart Panule (CITY)		
MAJOR PATHOPHYSIOLOGY	TYPICAL CHF MANIFESTATION*	
Myocardial Failure		
Idiopathic dilated cardiomyopathy Myocardial ischemia/infarction Drug toxicities (e.g., doxorubicin) Infective myocarditis	Either L- or R-CHF L-CHF L-CHF Either L- or R-CHF	
Volume-Flow Overload		
Mitral valve regurgitation (degenerative, congenital, infective)	L-CHF	
Aortic regurgitation (infective endocarditis, congenital)	L-CHF	
Ventricular septal defect	L-CHF	
Patent ductus arteriosus	L-CHF	
Tricuspid valve regurgitation (degenerative, congenital, infective)	R-CHF	
Tricuspid endocarditis	R-CHF	
Chronic anemia	Either L- or R-CHF	
Thyrotoxicosis	Either L- or R-CHF	
Pressure Overload		
(Sub)aortic stenosis	L-CHF	
Systemic hypertension	L-CHF (rare)	
Pulmonic stenosis	R-CHF	
Heartworm disease	R-CHF	
Pulmonary hypertension	R-CHF	
Impaired Ventricular Filling		
Hypertrophic cardiomyopathy	L-(+/- R-) CHF	
Restrictive cardiomyopathy	L-(+/ R-) CHF	
Cardiac tamponade	R-CHF	
Constrictive pericardial disease	R-CHF	

<sup>\*</sup> L-CHF, Left-sided congestive heart failure (pulmonary edema as main congestive sign); R-CHF, right-sided congestive heart failure (pleural effusion and/or ascites as main congestive sign). Weakness and other low-output signs can occur with any of these diseases, especially those associated with arrhythmias.

# APPROACH TO TREATING HEART FAILURE

Most current treatment strategies are aimed at modifying either the results of NH activation (i.e., sodium and water retention) or the activation process itself (e.g., ACE inhibition). In most cases, therapy centers on controlling edema and effusions, improving cardiac output, reducing cardiac workload, supporting myocardial function, and managing concurrent arrhythmias. The approach to these goals varies somewhat with different diseases, most notably those causing restriction to ventricular filling.

The evolving perspective on CHF management is based on blocking excessive NH activation and preventing progression of myocardial remodeling and dysfunction, with diuretics being used to control signs of congestion. Future strategies may also involve drugs that block cytokines, antagonize endothelins, and enhance atrial peptides, as well as other strategies to block the effects of NH activation.

## Classification of Severity

Guidelines for clinical staging of heart failure (based on the American Heart Association and American College of Cardiology [AHA/ACC] system) are being increasingly applied to veterinary patients (Table 3-2). These describe disease progression through four stages over time. This staging system emphasizes the importance of early diagnosis and evidence-based management of heart dysfunction. It also deemphasizes the term "congestive" in *congestive heart failure* because volume overload is not consistently present at all stages. Nevertheless, attention to the patient's fluid status is highly important.

The clinical severity of heart failure is also sometimes described according to a modified New York Heart Association (NYHA) classification scheme or the International Small Animal Cardiac Health Council (ISACHC) criteria. These systems group patients into functional categories on the basis of clinical observations rather than underlying cardiac disease or myocardial function. Such classification can be helpful conceptually and for categorizing study patients. Forrester's classification is another method of grouping heart failure patients. Dogs with chronic mitral regurgitation often fall into group II; severe dilated cardiomyopathy is the most common diagnosis in group IV. Diseases causing group III heart failure are rare in dogs and cats. Regardless of the clinical classification scheme, identifying the underlying etiology and pathophysiology, as well as the clinical severity, is important for individualized therapy.

# TREATMENT FOR ACUTE CONGESTIVE HEART FAILURE

#### **GENERAL CONSIDERATIONS**

Fulminant CHF is characterized by severe cardiogenic pulmonary edema, with or without pleural and/or abdominal effusions or poor cardiac output. Therapy is aimed at rapidly clearing pulmonary edema, improving oxygenation, and optimizing cardiac output (Box 3-1). Thoracocentesis should

TABLE 3-2

Classification Systems for Heart Failure Severity

CLASSIFICATION	DEGREE OF SEVERITY			
Modified AHA/ACC Heart Failure Staging System				
A	Patient "at risk" for the development of heart failure, but apparent cardiac structural abnormality not yet identified			
В	Structural cardiac abnormality is evident, but no clinical signs of heart failure			
С	Structural cardiac abnormality, with past or present clinical signs of heart failure			
D	Persistent or end-stage heart failure signs, refractory to standard therapy			
Modified NYHA Functional Classification				
1	Heart disease is present but no evidence of heart failure or exercise intolerance; cardiomegaly is minimal to absent			
<del>1</del> 1	Signs of heart disease with evidence of exercise intolerance; radiographic cardiomegaly is present			
111	Signs of heart failure with normal activity or at night (e.g., cough, orthopnea); radiographic signs of significant cardiomegaly and pulmonary edema or pleural/abdominal effusion			
IV	Severe heart failure with clinical signs at rest or with minimal activity; marked radiographic signs of CHF and cardiomegaly			
International Small Animal Cardiac Health Council Functional Classification				
1	Asymptomatic patient			
la	Signs of heart disease without cardiomegaly			
1b	Signs of heart disease and evidence of compensation (cardiomegaly)			
H	Mild to moderate heart failure. Clinical signs of failure evident at rest or with mild exercise, and adversely affect quality of life			
III	Advanced heart failure. Clinical signs of CHF are immediately obvious			
Illa	Home care is possible			
IIIb	Hospitalization recommended (cardiogenic shock, life-threatening edema, large pleural effusion, refractory ascites)			
Forrester's Classification (Group)				
1	Normal cardiac output and pulmonary venous pressures			
11	Pulmonary congestion but normal cardiac output			
III	Low cardiac output and peripheral hypoperfusion with no pulmonary congestion			
IV	Low cardiac output with pulmonary congestion			

AHA/ACC, American Heart Association and American College of Cardiology; CHF, congestive heart failure.

be performed expediently if marked pleural effusion exists. Likewise, large-volume ascites should be drained to improve ventilation. Animals with severe CHF are greatly stressed. Physical activity must be maximally curtailed to reduce total oxygen consumption; cage confinement is preferred. Environmental stresses such as excess heat and humidity or extreme cold should be avoided. When transported, the animal should be placed on a cart or carried. Unnecessary handling of the patient and administration of oral medications should be avoided, when possible.

### SUPPLEMENTAL OXYGEN

Oxygen administered by face mask or improvised hood, nasal catheter, endotracheal tube, or oxygen cage is beneficial as long as the method chosen does not increase the patient's distress. An oxygen cage with temperature and humidity controls is preferred, and a setting of 65°F is recommended for normothermic animals. Oxygen flow of 6 to 10 L/min is

usually adequate. Concentrations of 50% to 100% oxygen may be needed initially, but this should be reduced within a few hours to 40% to avoid lung injury. When a nasal tube is used, humidified O<sub>2</sub> is delivered at a rate of 50 to 100 ml/kg/min. Extremely severe pulmonary edema with respiratory failure may respond to endotracheal or tracheotomy tube placement, airway suctioning, and mechanical ventilation. Positive end-expiratory pressure helps clear small airways and expand alveoli. Positive airway pressures can adversely affect hemodynamics, however, and chronic high oxygen concentrations (>70%) can injure lung tissue (see Suggested Readings for more information). Continuous monitoring is essential for intubated animals.

# **DRUG THERAPY** Diuresis

Rapid diuresis can be achieved with IV furosemide; effects begin within 5 minutes, peak by 30 minutes, and last about

## Acute Treatment of Decompensated Congestive Heart Failure

Minimize patient stress!

Cage rest/transport on gurney (no activity allowed) Improve oxygenation:

Ensure airway patency

Give supplemental  $O_2$  (avoid >50% for >24 hours)

If frothing evident, suction airways

Intubate and mechanically ventilate if necessary

Thoracocentesis if pleural effusion suspected/documented

Remove alveolar fluid:

Diuresis:

Furosemide (dogs: 2-5[-8] mg/kg IV or IM, q1-4h until respiratory rate decreases, then 1-4 mg/kg q6-12h, or 0.6-1 mg/kg/h CRI [see text]; cats: 1-2[-4] mg/kg IV or IM, q1-4h until respiratory rate decreases, then q6-12h}

Redistribute blood volume:

Vasodilators (sodium nitroprusside, if able to monitor BP closely: 0.5-1 μg/kg/min CRI in D<sub>5</sub>W, titrate upward as needed to 5-15 μg/kg/min; or 2% nitroglycerin ointment—Dogs: <sup>1</sup>/<sub>2</sub> to 1<sup>1</sup>/<sub>2</sub> inch cutaneously q6h; cats: <sup>1</sup>/<sub>4</sub> to <sup>1</sup>/<sub>2</sub> inch cutaneously q6h)

±Morphine (dogs only, see below)

±Phlebotomy (6-10 ml/kg)

Minimize bronchoconstriction:

Aminophylline (dogs: 4-8 mg/kg slow IV, IM, SC, or 6-10 mg/kg PO q6-8h; cats: 4-8 mg/kg IM, SC, PO q8-12h) or similar drug

Reduce anxiety:

Butorphanol (dogs: 0.2-0.3 mg/kg IM; cats: 0.2-

0.25 mg/kg IM); or

Morphine (dogs: 0.025-0.1 mg/kg IV boluses q2-3min to effect, or 0.1-0.5 mg/kg single IM or SC dose)

Acepromazine (cats: 0.05-0.2 mg/kg SC; or 0.05-0.1 mg/kg IM with butorphanol), or

Diazepam (cats: 2-5 mg IV; dogs: 5-10 mg IV)

Reduce afterload:

Hydralazine (if not using nitroprusside; dogs: 0.5-1.0 mg/kg PO repeated in 2-3 hr [until systolic arterial pressure is 90-110 mm Hg], then q12h; see text); or

Enalapril (0.5 mg/kg PO q12-24h) or other ACEI—avoid nitroprusside; or

Amlodipine (dogs: 0.1-0.3 mg/kg PO, q12-24h; see text)

Increase contractility (if myocardial failure present):

Dobutamine\* (1-10 μg/kg/min CRI; start low), or dopamine† (dogs: 1-10 μg/kg/min CRI; cats: 1-5 μg/kg/min CRI; start low)

Amrinone (1-3 mg/kg IV; 10-100  $\mu$ g/kg/min CRI), or milrinone (50  $\mu$ g/kg IV over 10 minutes initially; 0.375-0.75  $\mu$ g/kg/minute CRI [human dose])

Pimobendan or digoxin PO (see Table 3-3); (digoxin loading dose [see text for indications]: PO—1 or 2 doses at twice calculated maintenance; dog IV: 0.01-0.02 mg/kg—give 1/4 of this total dose in slow boluses over 2-4 hours to effect; cat IV: 0.005 mg/kg—give 1/2 of total, then 1-2 hours later give 1/4 dose bolus(es), if needed)

Monitor and address abnormalities as possible:

Respiratory rate, heart rate and rhythm, arterial pressure, O<sub>2</sub> saturation, body weight, urine output, hydration, attitude, serum biochemistry and blood gas analyses, and pulmonary capillary wedge pressure (if available)

Diastolic dysfunction (e.g., cats with hypertrophic cardiomyopathy):

General recommendations, O<sub>2</sub> therapy, and furosemide as above

± Nitroglycerin and mild sedation

Consider IV esmolol (200-500 µg/kg IV over 1 minute, followed by 25-200 µg/kg CRI) or diltiazem (0.15-0.25 mg/kg over 2-3 minutes IV)

ACE, Angiotensin-converting enzyme; CRI, constant rate infusion;  $D_5W$ , 5% dextrose in water.

2 hours. This route also provides a mild venodilating effect. Some patients require aggressive initial doses or cumulative doses administered at frequent intervals (see Box 3-1). Furosemide can be given by constant rate infusion (CRI), which may provide greater diuresis than bolus injection. The veterinary formulation (50 mg/ml) can be diluted to 10 mg/ml for CRI using 5% dextrose in water (D₅W), lactated Ringer's solution (LRS), or sterile water. Dilution to 5 mg/ml in D₅W or sterile water is also described. The patient's respiratory rate, as well as other parameters (discussed in more detail later), guide the intensity of continued furosemide therapy. Once diuresis has begun and respiration improves, the dosage is reduced to prevent excessive volume contraction

or electrolyte depletion. An ancillary approach that has been described for patients with fulminant cardiogenic edema is phlebotomy (up to 25% of total blood volume), but this is not generally done.

#### Vasodilation

Vasodilator drugs can reduce pulmonary edema by increasing systemic venous capacitance, lowering pulmonary venous pressure, and reducing systemic arterial resistance. Although ACE inhibitors are a mainstay of CHF management, more immediate afterload reduction is desirable for animals with acute pulmonary edema. Arteriolar vasodilation is not recommended for heart failure

<sup>\*</sup>Dilution of 250 mg dobutamine into 500 ml of D<sub>5</sub>W or lactated Ringer's solution yields a solution of 500 μg/ml; CRI of 0.6 ml/kg/hr provides 5 μg/kg/min.

<sup>†</sup>Dilution of 40 mg of dopamine into 500 ml of D5W or lactated Ringer's solution yields a solution of 80 µg/ml; a volume of 0.75 ml/kg/hr provides 1 µg/kg/min.

caused by diastolic dysfunction or ventricular outflow obstruction.

Sodium nitroprusside is a potent arteriolar and venous dilator, with direct action on vascular smooth muscle. It is given by IV infusion because of its short duration of action. Blood pressure must be closely monitored when using this drug. The dose is titrated to maintain mean arterial pressure at about 80 mm Hg (at least >70 mm Hg) or systolic blood pressure between 90 and 110 mm Hg. Nitroprusside CRI is usually continued for 12 to 24 hours. Dosage adjustments may be needed because drug tolerance develops rapidly. Profound hypotension is the major adverse effect. Cyanide toxicity can result from excessive or prolonged use (e.g., longer than 48 hours). Nitroprusside should not be infused with other drugs, and should be protected from light.

Hydralazine, a pure arteriolar dilator, is an alternative to nitroprusside. It is useful for refractory pulmonary edema caused by mitral regurgitation (and sometimes dilated cardiomyopathy) because it can reduce regurgitant flow and lower left atrial pressure. An initial dose of 0.75 to 1 mg/kg is given orally, followed by repeated doses every 2 to 3 hours until the systolic blood pressure is between 90 and 110 mm Hg or clinical improvement is obvious. If blood pressure cannot be monitored, an initial dose of 1 mg/kg is repeated in 2 to 4 hours if sufficient clinical improvement has not been observed. The addition of 2% nitroglycerin ointment may provide beneficial venodilating effects.

An ACE inhibitor or amlodipine, with or without nitroglycerin ointment, is an alternative to hydralazine/nitroglycerine. The onset of action is slower and the effects are less pronounced, but this regimen can still be helpful.

Nitroglycerin (and other orally or transcutaneously administered nitrates) act mainly on venous smooth muscle to increase venous capacitance and reduce cardiac filling pressure. The major indication for nitroglycerin is acute cardiogenic pulmonary edema. Nitroglycerin ointment (2%) is usually applied to the skin of the groin, axillary area, or ear pinna, although the efficacy of this in heart failure is unclear. An application paper or glove is used to avoid skin contact by the person applying the drug.

## Other Acute Therapy

Some dogs with severe pulmonary edema and bronchoconstriction benefit from bronchodilator therapy. Aminophylline, given by slow IV administration or intramuscular (IM) injection, has mild diuretic and positive inotropic actions as well as a bronchodilating effect; it also decreases fatigue of respiratory muscles. Adverse effects include increased sympathomimetic activity and arrhythmias. The oral route can be used when respiration improves because gastrointestinal (GI) absorption is rapid.

Mild sedation (butorphanol or morphine for dogs, butorphanol with acepromazine for cats) can reduce anxiety. Because morphine can induce vomiting, butorphanol may be a better choice in dogs. Nevertheless, other beneficial effects of morphine include slower, deeper breathing from respiratory center depression and redistribution of blood

away from the lungs via dilation of capacitance vessels. Morphine is contraindicated in dogs with neurogenic edema because it can raise intracranial pressure. Morphine is not used in cats.

## **Inotropic Support**

Positive inotropic therapy is indicated when heart failure is caused by poor myocardial contractility. Oral therapy with pimobendan or digoxin can be started as soon as practical for animals needing chronic inotropic support (see Table 3-3 and p. 65). Treatment for one to three days with an IV sympathomimetic (catecholamine) or phosphodiesterase (PDE) inhibitor drug can help support arterial pressure, forward cardiac output, and organ perfusion when myocardial failure or hypotension is severe.

Catecholamines enhance contractility via a cAMP-mediated increase in intracellular Ca<sup>++</sup>. They can provoke arrhythmias and increase pulmonary and systemic vascular resistance (potentially exacerbating edema formation). Their short half-life (<2 minutes) and extensive hepatic metabolism necessitate constant IV infusion. Dobutamine (a synthetic analog of dopamine) has lesser effect on heart rate and afterload and is preferred over dopamine. Dobutamine stimulates  $\beta_1$ -receptors, with only weak action on  $\beta_2$ - and  $\alpha$ -receptors. Lower doses (e.g., 3 to 7 µg/kg/min) have minimal effects on heart rate and blood pressure. The initial infusion rate should be low; this can be gradually increased over hours to achieve greater inotropic effect and maintain systolic arterial pressure between 90 and 120 mm Hg. Heart rate, rhythm, and blood pressure must be monitored closely. Although dobutamine is less arrhythmogenic than other catecholamines, higher infusion rates (e.g., 10 to 20 µg/kg/min) can precipitate supraventricular and ventricular arrhythmias. Adverse effects are more likely in cats; these include seizures at relatively low doses.

Dopamine at low doses (<2-5  $\mu$ g/kg/minute) also stimulates vasodilator dopaminergic receptors in some regional circulations. Low-to-moderate doses enhance contractility and cardiac output, but high doses (10-15  $\mu$ g/kg/minute) cause peripheral vasoconstriction and increase heart rate, O<sub>2</sub> consumption, and the risk of ventricular arrhythmias. An initial IV infusion of 1  $\mu$ g/kg/min can be titrated upward to desired clinical effect. The infusion rate should be decreased if sinus tachycardia or other tachyarrhythmias develop.

Bipyridine PDE inhibitors such as amrinone and milrinone increase intracellular Ca<sup>++</sup> by inhibiting PDE III, an intracellular enzyme that degrades cAMP. These drugs also cause vasodilation, as increased cAMP promotes vascular smooth muscle relaxation. Hypotension, tachycardia, and GI signs can occur when giving high doses. These drugs can exacerbate ventricular arrhythmias. The effects of amrinone are short-lived (<30 minutes) after IV injection in normal dogs, so CRI is required for sustained effect. Peak effects occur after 45 minutes of CRI in dogs. Amrinone is sometimes used as an initial slow IV bolus followed by CRI; half the original bolus dose can be repeated after 20 or 30 minutes. Milrinone has a much greater potency than amrinone, but

#### Drugs for Managing Chronic Heart Failure

DRUG	DOGS	CATS
Diuretics		
Furosemide	1-3 mg/kg PO q8-24h (long term); use smallest effective dose	1-2 mg/kg PO q8-12h; use smallest effective dose
Spironolactone	0.5-2 mg/kg PO q(12-)24h	0.5-1 mg/kg PO q(12-)24h
Chlorothiazide	20-40 mg/kg PO q12h	20-40 mg/kg PO q12h
Hydrochlorothiazide	2-4 mg/kg PO q12h	1-2 mg/kg PO q12h
ACE Inhibitors		
Enalapril	0.5 mg/kg PO q(12-)24h	0.25-0.5 mg/kg PO q24(-12)h
Benazepril	0.25-0.5 mg/kg PO q(12-)24h	0.25-0.5 mg/kg PO q24(-12)h
Captopril	0.5-2.0 mg/kg PO q8-12h (low initial dose)	0.5-1.25 mg/kg PO q12-24h
Lisinopril Fosinopril	0.25-0.5 mg/kg PO q(12-)24h 0.25-0.5 mg/kg PO q24h	0.25-0.5 mg/kg PO q24h
Ramipril	0.125-0.25 mg/kg PO q24h	_
Imidapril	0.25 mg/kg PO q24h	_
Other Vasodilators		
Hydralazine Amlodipine Prazosin	0.5-2 mg/kg PO q12h (to 1 mg/kg initial) 0.05 (initial) to 0.3(-0.5) mg/kg PO q(12-)24h Medium dogs: 1 mg PO q8-12hr; large dogs:	2.5 (up to 10) mg/cat PO q12h 0.3125-0.625 mg/cat PO q24(-12)h
110203111	2 mg PO q8h	
Nitroglycerin 2% ointment	1/2- $11/2$ inch cutaneously q4-6h	$^{1}/_{4}$ - $^{1}/_{2}$ inch cutaneously q4-6h
Isosorbide dinitrate	0.5-2 mg/kg PO q(8-)12h	_
Isosorbide mononitrate	0.25-2 mg/kg PO q12h	_
Positive Inotropes		
Pimobendan	0.1-0.3 mg/kg PO q12h, start low; give at least 1 hour before feeding	
Digoxin	PO: dogs <22 kg, 0.005-0.008 mg/kg q12h; dogs >22 kg, 0.22 mg/m² or 0.003-0.005 mg/kg q12h. Decrease by 10% for elixir. Maximum: 0.5 mg/day or 0.375 mg/day for Doberman Pinchers. See Box 3-1 for loading doses.	0.007 mg/kg (or 1/4 of 0.125 mg tab) PO q48h. See Box 3-1 for IV dose.

CRI, Constant rate infusion.

there is little veterinary data with the IV form. A PDE inhibitor can be used concurrently with digoxin and a catecholamine.

Digoxin is generally not used intravenously except for some supraventricular tachyarrhythmias when other acute therapy is unavailable or ineffective (see Chapter 4). Acidosis and hypoxemia associated with severe pulmonary edema can increase myocardial sensitivity to digitalis-induced arrhythmias. If digoxin is used intravenously, it must be given slowly (over at least 15 minutes); rapid injection causes peripheral vasoconstriction. The calculated dose is usually divided, and boluses of one fourth the dose are given slowly over several hours.

If arrhythmias develop during IV inotropic therapy, the infusion rate is reduced or the drug is discontinued. In animals with atrial fibrillation, catecholamine infusion is

likely to increase the ventricular response rate by enhancing atrioventricular (AV) conduction. If dobutamine or dopamine is deemed necessary for such a case, diltiazem (administered rapidly by mouth or cautiously by IV) is used to reduce the heart rate. Digoxin, administered either by mouth (loading) or cautiously by IV, is an alternative.

# HEART FAILURE CAUSED BY DIASTOLIC DYSFUNCTION

When acute CHF is caused by hypertrophic cardiomyopathy, thoracocentesis (if needed), diuretics, and oxygen therapy are given as outlined previously. Cutaneous nitroglycerin can also be used. Diltiazem or a  $\beta_1$ -blocker such as atenolol can be given to slow heart rate and increase ventricular filling time once severe dyspnea has abated; alternatively, IV administration of diltiazem or esmolol could be used. Propranolol

(or other nonselective  $\beta$ -blockers) is generally avoided in patients with fulminant pulmonary edema because  $\beta_2$ -blockade could induce bronchoconstriction.

Arteriolar vasodilators can be detrimental if dynamic left ventricular (IV) outflow obstruction coexists, because afterload reduction provokes greater systolic obstruction (see Chapter 8). ACE inhibitors at standard doses do not appear to worsen the IV outflow gradient. Addition of an ACE inhibitor is recommended as soon as oral therapy is possible.

### MONITORING AND FOLLOW-UP

Repeated assessment is important to monitor the effectiveness of therapy and to prevent hypotension or severe azotemia caused by excessive diuresis. Mild azotemia commonly occurs. Hypokalemia and metabolic alkalosis can occur after aggressive diuresis. A serum potassium concentration within the mid- to high-normal range is especially important for animals with arrhythmias. Serum biochemical testing every 24 to 48 hours is advised until the patient is eating and drinking well.

Arterial blood pressure can be monitored indirectly or directly, but gaining arterial access can increase patient stress. Indirect measures of organ perfusion such as capillary refill time, mucous membrane color, urine output, toe-web temperature, and mentation can also be useful. Body weight should be monitored, especially with aggressive diuretic therapy.

Central venous pressure (CVP) does not adequately reflect left heart filling pressures. It should not be used to guide diuretic or fluid therapy in patients with cardiogenic pulmonary edema. Although pulmonary capillary wedge pressure can reliably guide therapy, the placement and care of an indwelling pulmonary artery catheter require meticulous attention to asepsis and close monitoring.

Pulse oximetry is a helpful noninvasive means of monitoring oxygen saturation (SpO<sub>2</sub>). Supplemental O<sub>2</sub> should be given if SpO<sub>2</sub> is <90%; mechanical ventilation is indicated if SpO<sub>2</sub> is <80% despite O<sub>2</sub> therapy. Arterial sampling for blood gas analysis is more accurate but is stressful for the patient. Resolution of radiographic evidence for pulmonary edema usually lags behind clinical improvement by a day or two.

After respiratory signs begin to abate and diuresis is evident, low-sodium water is offered. Fluid administration (either subcutaneously or intravenously) is generally not advised in patients with fulminant CHF. In most cases, gradual rehydration by free choice (low sodium) water intake is preferred even after aggressive diuretic therapy. However, fluid therapy may be necessary for patients with heart failure and renal failure, marked hypokalemia, hypotension, digoxin toxicity, persistent anorexia, or other serious systemic disease. Some animals require relatively high cardiac filling pressure to maintain cardiac output, especially those with myocardial failure or markedly reduced ventricular compliance (e.g., from hypertrophic cardiomyopathy or pericardial disease). Diuresis and vasodilation in such cases can cause inadequate cardiac output and hypotension.

In most patients with decompensated CHF, the smallest fluid volume possible should be used to deliver drugs by CRI. Careful monitoring and continued diuretic use is important to prevent recurrent pulmonary edema. When additional fluid therapy is necessary, D<sub>5</sub>W or a reduced sodium fluid (e.g., 0.45% NaCl with 2.5% dextrose) with added KCl is administered at a conservative rate (e.g., 15 to 30 ml/kg/day IV). Alternatively, 0.45% NaCl with 2.5% dextrose or lactated Ringer's solution can be administered subcutaneously.

Potassium supplementation at a maintenance rate is provided by 0.05 to 0.1 mEq/kg/hour (or more conservatively, 0.5 to 2.0 mEq/kg/day). For animals with hypokalemia, higher rates are used: 0.15 to 0.2 mEq/kg/hour for mild K deficiency; 0.25 to 0.3 mEq/kg/hour for moderate deficiency; and 0.4 to 0.5 mEq/kg/hour for severe deficiency. Measuring serum K' concentration in 4 to 6 hours is advised when supplementing for moderate to severe deficiency. Hyponatremia and worsened fluid retention can develop after using low-sodium IV solutions in some patients. These require a more balanced crystalloid solution. Other supportive therapies for CHF and any underlying disease(s) depend on individual patient needs. Parenteral fluid administration is tapered off as the animal is able to resume oral food and water intake.

# MANAGEMENT OF CHRONIC HEART FAILURE

## **GENERAL CONSIDERATIONS**

A general approach to chronic heart failure therapy is presented in this section. Additional information is found in the chapters describing different diseases. Therapy is tailored to the individual animal's needs by adjusting dosages, adding or substituting drugs, and modifying lifestyle or diet. Pleural effusion and large-volume ascites that accumulate despite medical therapy should be drained to facilitate respiration. Likewise, pericardial effusion that compromises cardiac filling must be drained. As heart disease progresses, more aggressive therapy is usually needed. Support of cardiac function with digoxin or pimobendan is often indicated in dogs and sometimes in cats.

Exercise restriction helps reduce cardiac workload regardless of heart failure etiology. Strenuous exercise can provoke dyspnea and potentially serious cardiac arrhythmias even in animals with compensated CHE. Chronic heart failure is associated with skeletal muscle changes that lead to fatigue and dyspnea. Physical training can improve cardiopulmonary function and quality of life in patients with chronic heart failure. This is partly mediated by improvement in vascular endothelial function and restoration of flow-dependent vasodilation. Although it is difficult to know how much exercise is best, regular (not sporadic) mild to moderate activity is encouraged, as long as excessive respiratory effort is not induced. Bursts of strenuous activity should be avoided. Dietary salt restriction and other nutritional issues are also

important in the management of patients with chronic heart failure.

#### **DIURETICS**

Diuretic therapy is indicated for controlling cardiogenic pulmonary edema and effusions. Diuretics remain fundamental to the management of CHF because of their ability to decrease venous congestion and fluid accumulation (see Table 3-3). Agents that interfere with ion transport in the loop of Henle (e.g., furosemide) have potent ability to promote both salt and water loss. Diuretics of other classes, such as thiazides and potassium-sparing agents, are sometimes combined with furosemide for chronic heart failure therapy. Given to excess, diuretics promote excessive volume contraction and activate the renin-angiotensin-aldosterone cascade. Diuretics also can exacerbate preexisting dehydration or azotemia. Therefore the indication for their use in such animals should be clearly established, and the lowest effective dose should be used.

#### **Furosemide**

Furosemide is the loop diuretic used most widely for cats and dogs with heart failure. It acts on the ascending limb of the loop of Henle to inhibit active Cl<sup>-</sup>, K<sup>+</sup>, and Na<sup>-</sup> cotransport, thereby promoting excretion of these electrolytes; Ca<sup>++</sup> and Mg<sup>-+</sup> are also lost in the urine. Loop diuretics can increase systemic venous capacitance, possibly by mediating renal prostaglandin release. Furosemide may also promote salt loss by increasing total renal blood flow and by preferentially enhancing renal cortical flow. The loop diuretics are well absorbed when given orally. After oral administration, diuresis occurs within 1 hour, peaks between 1 to 2 hours, and may last for 6 hours. Furosemide is highly protein bound; about 80% is actively secreted unchanged in the proximal renal tubules, with the remainder excreted as glucuronide.

Although aggressive furosemide treatment is indicated for acute, fulminant pulmonary edema, the smallest effective doses should be used for chronic heart failure therapy. The dosage varies, depending on the clinical situation. Respiratory pattern, hydration, body weight, exercise tolerance, renal function, and serum electrolyte concentrations are used to monitor response to therapy. Furosemide (or other diuretic) alone is not recommended as the sole treatment for chronic heart failure because it can exacerbate NH activation and reduce renal function.

Adverse effects are usually related to excessive fluid and/or electrolyte losses. Because they are more sensitive than dogs, lower doses are used in cats. Although hypokalemia is the most common electrolyte disturbance, it is unusual in dogs that are not anorexic. Hyponatremia develops in some patients with severe CHF and results from an inability to excrete free water (dilutional hyponatremia) rather than from a total body sodium deficit.

## **Spironolactone**

Spironolactone may be a useful adjunct therapy in patients with chronic refractory heart failure. Its anti-aldosterone

effects are also thought to be important locally within the heart. Spironolactone is a competitive antagonist of aldosterone. It promotes Na\* loss and K\* retention in the distal renal tubule and can reduce the renal potassium wasting of furosemide and other diuretics, especially when circulating aldosterone concentration is high. But its diuretic effect in normal dogs is questionable. Spironolactone's onset of action is slow; peak effect occurs within 2 to 3 days.

Aldosterone release can occur despite the use of an ACE inhibitor (so-called aldosterone escape); this may involve reduced hepatic clearance, increased release stimulated by K<sup>+</sup> elevation or Na<sup>+</sup> depletion, and local tissue aldosterone production. Spironolactone's anti-aldosterone effect is thought to mitigate aldosterone-induced cardiovascular remodeling in some cases. The drug has improved survival in people with moderate to severe CHF, but it is not yet clear whether similar survival benefit occurs clinically in dogs and cats.

A potassium-sparing diuretic must be used cautiously in patients receiving an ACE inhibitor or potassium supplement and is absolutely contraindicated in hyperkalemic patients. Adverse effects relate to excess K<sup>+</sup> retention and GI disturbances. Spironolactone may decrease digoxin clearance.

### **Thiazide Diuretics**

Thiazide diuretics decrease Na and Cl absorption and increase Ca absorption in the distal convoluted tubules. Mild to moderate diuresis with excretion of Na , Cl , K , and Mg results. The thiazides decrease renal blood flow and should not be used in azotemic animals. Adverse effects are uncommon in the absence of azotemia, but hypokalemia or other electrolyte disturbance and dehydration can occur with excessive use or in anorectic patients. Thiazides can cause hyperglycemia in diabetic or prediabetic animals by inhibiting conversion of proinsulin to insulin. Chlorothiazide's effects begin within 1 hour, peak at 4 hours, and last 6 to 12 hours. Hydrochlorothiazide produces diuresis within 2 hours, with peak effect at 4 hours, and duration of about 12 hours.

# ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

ACE inhibitors (ACEIs) are indicated for most causes of chronic heart failure, especially dilated cardiomyopathy and chronic valvular insufficiency (see Table 3-3). Their use has led to clinical improvement and lowered mortality rates in people with heart failure; similar benefits seem to occur in dogs with myocardial failure or volume overload and in cats with diastolic dysfunction. They moderate excess NH responses in several ways; therefore ACEIs have considerable advantages over hydralazine and other arteriolar dilators. ACEIs have only modest diuretic and vasodilatory effects; their main benefits arise from opposing the effects of NH activation and abnormal cardiovascular remodeling changes. By blocking the formation of angiotensin II, ACEIs allow arteriolar and venous vasodilation. The secondary inhibition of aldosterone release helps reduce Na<sup>+</sup> and water retention

and therefore edema/effusions, as well as the adverse effects of aldosterone directly on the heart. ACEIs reduce ventricular arrhythmias and the rate of sudden death in people (and probably animals) with heart failure, likely because angiotensin II—induced facilitation of norepinephrine and epinephrine release is inhibited. Their vasodilating effects may be enhanced by vasodilator kinins normally degraded by ACE. A local vasodilating effect may occur through inhibition of ACE found within vascular walls, even in the absence of high circulating renin concentrations. Local ACE inhibition may be beneficial by modulating vascular smooth muscle and myocardial remodeling. However, it is unclear whether ACE inhibitors prevent ventricular remodeling and dilation in dogs with heart disease. ACE inhibitors have been variably effective in treating dogs with hypertension.

Most ACEIs (except captopril and lisinopril) are prodrugs that are converted to their active form in the liver; therefore severe liver dysfunction can interfere with this conversion. Adverse effects of ACEIs include hypotension, GI upset, deterioration of renal function, and hyperkalemia (especially when used with a potassium-sparing diuretic or potassium supplement). Angiotensin II is important in mediating renal efferent arteriolar constriction, which maintains glomerular filtration when renal blood flow decreases. As long as cardiac output and renal perfusion improve with therapy, renal function is usually maintained. Poor glomerular filtration is more likely to result with overdiuresis, excess vasodilation, or severe myocardial dysfunction. Azotemia is first addressed by decreasing the diuretic dosage. If necessary, the ACEI dosage is decreased or discontinued. Hypotension can usually be avoided by starting with low initial doses. Other adverse effects reported in people include rash, pruritus, impairment of taste, proteinuria, cough, and neutropenia. The mechanism of ACEI-induced cough in people is unclear but may involve inhibition of endogenous bradykinin degradation or may be associated with increased NO generation. NO has an inflammatory effect on bronchial epithelial cells.

## **Enalapril**

Enalapril maleate is absorbed well when taken orally; administration with food does not decrease its bioavailability. It is hydrolyzed in the liver to enalaprilat, its most active form. Peak ACE-inhibiting activity occurs within 4 to 6 hours in dogs. Duration of action is 12 to 14 hours, and effects are minimal by 24 hours at the recommended once-daily dose. Enalapril is generally administered once daily, although some dogs respond better when dosed every 12 hours. In cats maximal activity occurs within 2 to 4 hours after an oral dose of either 0.25 or 0.5 mg/kg; some ACE inhibition (50% of control) persists for two to three days. Enalapril and its active metabolite are excreted in the urine. Renal failure and severe CHF prolong its half-life, so reduced doses or benazepril are used in such patients. Severe liver dysfunction will interfere with the conversion of the prodrug to the active enalaprilat; lisinopril or captopril should be considered in such patients instead. Injectable enalaprilat is also available, but little veterinary data exist on its use; this form is not well absorbed orally.

## Benazepril

Benazepril is metabolized to its active form, benazeprilat. Only about 40% is absorbed when administered orally, but feeding does not affect absorption. After oral administration, peak ACE inhibition occurs within 2 hours in dogs and cats; its effect can last over 24 hours. In cats doses of 0.25 to 0.5 mg/kg result in 100% inhibition of ACE that is maintained at >90% for 24 hours, and tapers off to about 80% by 36 hours. Benazapril has an initial half-life of 2.4 hours and terminal half-life of about 29 hours in cats. Repeated doses produce moderate increases in drug plasma concentration. Benazepril is a preferred ACEI for animals with renal disease. This drug is climinated equally in urine and bile in dogs. In cats about 85% of the drug is excreted in the feces and only 15% in urine. The drug is generally well tolerated. It may also slow renal function deterioration in cats with kidney disease.

## Captopril

Captopril was the first ACEI used clinically. Captopril contains a sulfhydryl group, in contrast to enalapril and others. Disulfide metabolites can act as free radical scavengers. This might have beneficial effects for the treatment of some heart diseases, although the clinical significance is presently unclear. Captopril appears to be less effective than several other agents in reducing ACE activity in normal dogs. Captopril is well absorbed when taken orally (75% bioavailable); however, food decreases its bioavailability by 30% to 40%. In dogs hemodynamic effects appear within 1 hour, peak in 1 to 2 hours, and last less than 4 hours. Captopril is excreted in the urine.

### Lisinopril

Lisinopril is a lysine analog of enalaprilat with direct ACE-inhibiting effects. It is 25% to 50% bioavailable, and absorption is not affected by feeding. The time to peak effect is 6 to 8 hours. The duration of ACE inhibition appears long, but more specific information in animals is lacking. Once-daily administration has been tried with apparent effectiveness.

## **Fosinopril**

Fosinopril is structurally different in that it contains a phosphinic acid radical (rather than sulfhydryl or carboxyl), and it may be retained longer in myocytes. Fosinopril is also a prodrug that is converted to the active fosinoprilat in the GI mucosa and liver. Elimination occurs equally between kidney and liver; compensatory increases in one pathway occur with impairment of the other. Its duration of action is well over 24 hours in people. Fosinopril may cause falsely low scrum digoxin measurements using certain RIA assays.

## Other Angiotensin-Converting Enzyme Inhibitors

Other agents that have been used in animals with heart failure include ramipril, quinipril, and imidapril. The latter is comparable to enalapril in efficacy and is available in liquid form, although other ACEIs can be compounded into suspension.

#### POSITIVE INOTROPIC AGENTS

A positive inotropic agent is indicated for patients with dilated cardiomyopathy or other causes of myocardial failure, including dogs with advanced mitral regurgitation (see Table 3-3). Pimobendan, now approved in the United States, and digoxin are the inotropic agents available for chronic oral therapy. Pimobendan improves cardiac pump function both by enhancing contractility as well as by vasodilation. Digoxin is still used in some cases and can be combined with pimobendan. Digoxin also is indicated for treating some supraventricular tachyarrhythmias (see Chapter 4), except in cats with hypertrophic cardiomyopathy.

#### Pimobendan

Pimobendan (Vetmedin) is a benzimidazole-derivative phosphodiesterase III inhibitor. It slows cAMP breakdown and enhances adrenergic effects on Ca++ fluxes and myocardial contractility. Pimobendan also has a calcium-sensitizing effect on the contractile proteins, which promotes increased contractility without an increase in myocardial O2 requirement. Pimobendan is known as an inodilator because it increases contractility while also causing systemic and pulmonary vasodilation. The drug may have other beneficial effects by modulating NH and proinflammatory cytokine activation. Peak plasma concentrations occur within an hour of oral dosing. Bioavailability is about 60% in dogs, but this decreases in the presence of food. Pimobendan is highly protein bound. Elimination is mainly via hepatic metabolism and biliary excretion. Concurrent Ca<sup>++</sup> or β-blocker therapy may diminish the drug's positive inotropic effect.

Clinical improvement has occurred in many dogs when this agent was added to conventional CHF therapy (e.g., furosemide, an ACE inhibitor, and digoxin). Pimobendan appears to improve clinical status and increase survival time in dogs with dilated cardiomyopathy (DCM) or chronic mitral valve disease. Pimobendan does not appear to increase the frequency of ventricular arrhythmias and sudden death, as has occurred with other phosphodiesterase inhibitors. There are limited anecdotal reports of pimobendan use in cats.

#### Digoxin

The benefits of digoxin arise from its modest positive inotropic effect as well as its supraventricular antiarrhythmic activity. Its ability to sensitize baroreceptors and thereby modulate neurohormonal activation is probably its most important attribute in patients with heart failure. Because digoxin is potentially toxic, low doses are used and serum concentrations should be monitored. Serum concentrations in the low to mid therapeutic range are desired (discussed in more detail later).

Digoxin is indicated in patients with heart failure caused by myocardial dysfunction, chronic mitral insufficiency, and other chronic volume or pressure overloads. Digoxin is usually contraindicated in patients with hypertrophic cardiomyopathy, especially those with ventricular outflow obstruction; it is not useful in dogs or cats with pericardial diseases. Digoxin is only moderately effective in slowing the ventricular response rate to atrial fibrillation and does not cause conversion to sinus rhythm. It is usually contraindicated when sinus or AV node disease is present. Digoxin is relatively contraindicated in most patients with serious ventricular arrhythmias because it can exacerbate such arrhythmias.

Digoxin, in addition to other digitalis glycosides, increases the Ca<sup>++</sup> available to contractile proteins by competitively binding and inhibiting the Na<sup>+</sup>, K<sup>+</sup>-ATPase pump at the myocardial cell membrane. Intracellular Na<sup>+</sup> accumulation then promotes Ca<sup>++</sup> entry via the sodium-calcium exchange. In diseased myocardial cells in which diastolic sequestration and systolic release of Ca<sup>++</sup> is impaired, digitalis glycosides may be ineffective as inotropic agents and could predispose the patient to cellular Ca<sup>++</sup> overload and electrical instability.

The antiarrhythmic effects of digoxin are mediated primarily via increased parasympathetic tone to the sinus and AV nodes and the atria. Some direct effects further prolong conduction time and refractory period of the AV node. Sinus rate slowing, reduced ventricular response rate to atrial fibrillation and flutter, and suppression of atrial premature depolarizations are resulting effects. Although some ventricular arrhythmias might be suppressed (probably via enhanced vagal tone), the digitalis glycosides have potential arrhythmogenic effects, especially in patients with heart failure.

Oral maintenance doses of digoxin are used to initiate therapy in most cases because loading doses can result in toxic serum concentrations. When more rapid achievement of therapeutic serum concentrations is important (e.g., for supraventricular tachyarrhythmia), the drug can be given at twice the oral maintenance dose for 1 to 2 doses or intravenously with caution (see Table 3-3). But alternate IV therapy for supraventricular tachycardia is usually more effective (see Chapter 4). Other IV-positive inotropic drugs (see p. 60 and Box 3-1) are safer and more effective than digoxin for immediate support of myocardial contractility.

Digoxin is well absorbed orally and undergoes minimal hepatic metabolism. Absorption is approximately 60% for the tablet form and 75% for the elixir. Bioavailability is decreased by kaolin-pectin compounds, antacids, the presence of food, and malabsorption syndromes. About 27% of the drug in serum is protein bound. The serum half-life in dogs ranges from 23 to 39 hours; therapeutic serum concentrations are achieved within 2 to 4½ days with dosing every 12 hours. In cats the reported serum half-life ranges widely, from about 25 to over 78 hours; chronic oral administration increases the half-life. The alcohol-based elixir, which is poorly palatable, results in serum concentrations approximately 50% higher than the tablet form of digoxin. Administration of the tablets with food has resulted in serum

concentrations about 50% lower than in the fasted state in cats. The pharmacokinetics in cats with heart failure are similar to those in control cats receiving aspirin, furosemide, and a low-salt diet, although much interpatient variation is present. Digoxin treatment every 48 hours in cats produces effective serum concentrations, with steady state achieved in about 10 days. Because approximately 50% of cats become toxic at a dose of 0.01 mg/kg every 48 hours, a dose of 0.007 mg/kg every 48 hours has been recommended. Serum concentrations can be measured 8 hours postdosing once steady state is reached (after about 10 days). Digoxin elimination is primarily by glomerular filtration and renal secretion in dogs, although approximately 15% is metabolized by the liver. Renal and hepatic elimination appear equally important in cats.

Serum digoxin concentration (and risk of toxicity) increases with renal failure because of reduced clearance and volume of distribution. There appears to be no correlation between the degree of azotemia and the serum digoxin concentration in dogs, making extrapolations from human formulas for calculating drug dosage in renal failure unusable in this species. Lower doses and close monitoring of serum digoxin concentration are recommended in animals with renal disease.

There is only a weak correlation between digoxin dose and serum concentration in dogs with heart failure, indicating that other factors influence the serum concentrations of this drug. Because much of the drug is bound to skeletal muscle, animals with reduced muscle mass or cachexia and those with compromised renal function can easily become toxic at the usual calculated doses. The dose should be based on the patient's calculated lean body weight because digoxin has poor lipid solubility. This consideration is especially important in obese animals. Management of digoxin toxicity is outlined later in this section. Conservative dosing and measurement of serum digoxin concentrations help to prevent toxicity.

Measurement of serum concentration is recommended 7 to 10 days after initiation of therapy (or dosage change). Samples should be drawn 8 to 10 hours postdose. Many veterinary and most human hospital laboratories can provide this service. The therapeutic serum concentration range is 1 to 2 (or 2.4) ng/ml. If the serum concentration is less than 0.8 ng/ml, the digoxin dose can be increased by 25% to 30% and the serum concentration measured the following week. But a serum concentration in the mid to low therapeutic range is probably safer. People with high-normal serum digoxin concentrations have greater risk for sudden death. If serum concentrations cannot be measured and toxicity is suspected, the drug should be discontinued for one to two days and then reinstituted at half of the original dose.

Certain drugs affect serum digoxin concentrations when administered concurrently. Quinidine increases serum digoxin concentrations by displacing the drug from skeletal muscle binding sites and reducing its renal clearance. This drug combination is therefore not recommended, but, if both must be used, the digoxin dose is reduced by 50% initially and guided by serum concentration measurement. Other drugs known to increase serum digoxin concentration include verapamil and amiodarone. Diltiazem, prazosin, spironolactone, and triamterene possibly increase serum digoxin concentration. Hypokalemia especially, as well as other electrolyte and thyroid disturbances, can potentiate digoxin toxicity. Drugs affecting hepatic microsomal enzymes may also have effects on digoxin metabolism.

## **Digoxin Toxicity**

As discussed previously, azotemia, hypokalemia, or concurrent use of certain drugs predispose the patient to digoxin toxicity. Therefore it is important to monitor renal function and serum electrolytes during digoxin therapy. Hypokalemia predisposes the patient to myocardial toxicity by leaving more available binding sites on membrane Nat, K+-ATPase for digitalis; conversely, hyperkalemia displaces digitalis from those binding sites. Hypercalcemia and hypernatremia potentiate both the inotropic and the toxic effects of the drug. Abnormal thyroid hormone concentrations can also influence the response to digoxin. Hyperthyroidism may potentiate the myocardial effects of the drug, whereas hypothyroidism prolongs the half-life of digoxin in people but has no pharmacokinetic effect in dogs. Hypoxia sensitizes the myocardium to the toxic effects of digitalis. Quinidine increases serum digoxin concentration by reducing renal clearance and competing for Na/K binding sites in skeletal muscle. Verapamil and amiodarone also increase serum digoxin concentration; other drugs that may do so include diltiazem, prazosin, and spironolactone. In addition, alteration of hepatic and renal function may affect the clearance of these drugs.

Digoxin toxicity causes GI, myocardial, or sometimes central nervous system (CNS) signs. GI toxicity may develop before signs of myocardial toxicity. Signs include anorexia, depression, vomiting, borborygmi, and diarrhea. Some of these GI signs result from the direct effects of digitalis on chemoreceptors in the area postrema of the medulla. CNS signs include depression and disorientation.

Myocardial toxicity from digitalis glycosides can cause almost any cardiac rhythm disturbance, including ventricular tachyarrhythmias, supraventricular premature complexes and tachycardia, sinus arrest, Mobitz type I second-degree AV block, and junctional rhythms. Myocardial toxicity can occur before any other signs and can lead to collapse and death, especially in animals with myocardial failure. Therefore the appearance of PR interval prolongation or signs of GI toxicity should not be used to guide progressive dosing of digoxin. Digitalis glycosides can aggravate cellular calcium overloading and electrical instability common in failing myocardial cells. Digitalis can stimulate spontaneous automaticity of myocardial cells by inducing and potentiating late afterdepolarizations; cellular stretch, calcium overloading, and hypokalemia enhance this effect. Toxic concentrations of digitalis also enhance automaticity by increasing sympathetic tone to the heart. Furthermore, the parasympathetic effects of slowed conduction and altered refractory period facilitate development of reentrant arrhythmias. Digitalis intoxication should be suspected in patients taking the drug when ventricular arrhythmias and/or tachyarrhythmias with impaired conduction appear.

Therapy for digitalis toxicity depends on its manifestations. GI signs usually respond to drug withdrawal and correction of fluid or electrolyte abnormalities. AV conduction disturbances resolve after drug withdrawal, although sometimes anticholinergic therapy is needed. Digitalis-induced ventricular tachycardia and frequent ventricular premature complexes are generally treated with lidocaine. This drug reduces sympathetic nervous tone and can suppress arrhythmias caused by reentry and late afterdepolarizations; it has little effect on sinus rate or AV nodal conduction. If lidocaine is ineffective, phenytoin (diphenylhydantoin) is the second drug of choice in dogs; its effects are similar to those of lidocaine. IV administration of phenytoin must be slow to prevent hypotension and myocardial depression caused by the propylene glycol vehicle. Phenytoin has occasionally been used orally to treat or prevent ventricular tachyarrhythmias caused by digitalis.

Other measures are also helpful for digoxin toxicity, including IV potassium supplementation if the serum potassium concentration is <4 mEq/L (see p. 62). Magnesium supplementation may also be effective in suppressing arrhythmias; MgSO<sub>4</sub> has been used at 25 to 40 mg/kg via slow intravenous bolus, followed by infusion of the same dose over 12 to 24 hours. Fluid therapy is indicated to correct dehydration and maximize renal function. A β-blocker may help control ventricular tachyarrhythmias, but this is not used if AV conduction block is present. Quinidine should not be used because it increases the serum concentration of digitalis. Oral administration of the steroid-binding resin cholestyramine is useful only very soon after accidental overdose of digoxin because this drug undergoes minimal enterohepatic circulation. A preparation of digoxin-specific antigen-binding fragments (digoxin-immune Fab) derived from ovine antidigoxin antibodies has occasionally been used for digoxin and digitoxin overdose. The Fab fragment binds with antigenic determinants on the digoxin molecule, preventing and reversing the pharmacologic and toxic effects of digoxin. The Fab fragment-digoxin complex is subsequently excreted by the kidney. Each 38 mg vial will bind about 0.6 mg digoxin. The recommended human dose is: # vials needed = (serum digoxin concentration  $[ng/ml] \times$ body weight [kg])/100. A modified formula (Senior et al, 1991) taking the volume of distribution of digoxin in the dog into account is: # vials needed = body load of digoxin (mg)/0.6 mg of digoxin. The body load of digoxin = (serum digoxin concentration [ng/ml] /1000)  $\times$  14 L/kg  $\times$  body weight [kg].

## OTHER VASODILATORS

Vasodilators can affect arterioles, venous capacitance vessels, or both ("balanced" vasodilators). Arteriolar dilators relax arteriolar smooth muscle and thereby decrease systemic vas-

cular resistance and afterload on the heart. This facilitates ejection of blood and also can be useful in treating animals with hypertension. In patients with mitral regurgitation, arteriolar dilators decrease the systolic pressure gradient across the mitral valve, reduce regurgitant flow, and enhance forward flow into the aorta. Reduced regurgitant flow can diminish left atrial pressure, pulmonary congestion, and possibly left atrial size.

Arteriolar or mixed vasodilator therapy is generally begun with low doses to avoid hypotension and reflex tachycardia. Reduction in concurrent diuretic dosage may be advisable. Monitoring for signs of hypotension is especially important. Sequential arterial blood pressure measurement for several hours after dosage increase is preferred. A mean arterial pressure of 70 to 80 mm Hg or a venous pO<sub>2</sub> of >30 mm Hg (from a free-flowing jugular vein) is the suggested therapeutic goal for dosage titration. Systolic pressures of less than 90 to 100 mm Hg should be avoided. Clinical signs of druginduced hypotension include weakness, lethargy, tachycardia, and poor peripheral perfusion. The vasodilator dose can be titrated upward, if necessary, while monitoring for hypotension with each increase in dose.

Venodilators relax systemic veins, increase venous capacitance, decrease cardiac filling pressures (preload), and reduce pulmonary congestion. Goals of venodilator therapy are to maintain central venous pressure at 5 to 10 cm  $\rm H_2O$  and pulmonary capillary wedge pressure at 12 to 18 mm  $\rm Hg$ .

## Hydralazine

Hydralazine directly relaxes arteriolar smooth muscle when the vascular endothelium is intact, but it has little effect on the venous system. The drug reduces arterial blood pressure, improves pulmonary edema, and increases jugular venous oxygen tension (presumably from increased cardiac output) in dogs with mitral insufficiency and heart failure. The most common indication for hydralazine is acute, severe CHF from mitral regurgitation. Hydralazine has been associated with significant reflex tachycardia in some animals; the dosage should be reduced if this occurs. Hydralazine can contribute to the enhanced NH response in patients with heart failure, which makes it less desirable than ACEIs for chronic use. However, it can be useful for animals that cannot tolerate an ACEI.

Hydralazine has a faster onset of action than amlodipine. Its effect peaks within 3 hours and lasts up to 12 hours. Administration of hydralazine with food decreases bioavailability by over 60%. There is also extensive first-pass hepatic metabolism of this drug. However, in dogs increased doses saturate this mechanism and increase bioavailability. General precautions for initiating and titrating therapy are outlined in the preceding section.

Hypotension is the most common adverse effect of hydralazine therapy. GI upset also can occur, which may require drug discontinuation. High dosages have been associated with a lupuslike syndrome in people, although this has not been reported in animals.

## **Amlodipine**

This dihydropyridine L-type Ca<sup>+-</sup> channel blocker causes peripheral vasodilation as its major action, which tends to offsets any negative inotropic effect. Amlodipine has little effect on AV conduction. Besides being used to treat hypertension in cats and sometimes dogs (see Chapter 11), it is an adjunctive therapy for refractory CHF. In dogs that cannot tolerate ACEIs, amlodipine could be used in combination with a nitrate.

Amlodipine's oral bioavailability is good. It has a long duration of action (at least 24 hours in dogs). Plasma concentration peaks in 3 to 8 hours; half-life is about 30 hours. Plasma concentrations increase with long-term therapy. Maximal effect develops over 4 to 7 days after therapy is begun in dogs. The drug is metabolized in the liver. Elimination is through the urine and feces. Because of the delay in achieving maximum effect, low initial doses and weekly blood pressure monitoring during slow up-titration are recommended.

#### **Prazosin**

Prazosin selectively blocks  $\alpha_1$ -receptors in both arterial and venous walls. It is not often used for chronic CHF management because drug tolerance can develop over time and the capsule dose-size is inconvenient in small animals. In addition, controlled clinical studies in dogs are lacking. Hypotension is the most common adverse effect, especially after the first dose. Tachycardia should occur less frequently than with hydralazine because presynaptic  $\alpha_2$ -receptors, important in the feedback control of norepinephrine release, are not blocked.

## **Nitrates**

Nitrates act as venodilators. They are metabolized in vascular smooth muscle to produce NO, which indirectly mediates vasodilation. Nitroglycerin ointment or isosorbide dinitrate are used occasionally in the management of chronic CHF, either combined with standard therapy for refractory CHF or with hydralazine or amlodipine in animals that cannot tolerate ACEIs. Nitrates effect blood redistribution in people, but there are few studies involving dogs, especially using the oral route for CHF management. There is extensive first-pass hepatic metabolism, and the efficacy of oral nitrates is questionable. Nitroglycerine ointment (2%) is usually applied cutaneously (see p. 60). Self-adhesive, sustained-release preparations may be useful, but they have not been systematically evaluated in small animals. Transdermal patches, 5 mg, applied for 12 hours per day, have been used with anecdotal success in large dogs. Large doses, frequent application, or long-acting formulations are most likely to be associated with drug tolerance. Whether intermittent treatment (with drug-free intervals) will prevent nitrate tolerance from developing in dogs and cats is unknown.

#### **DIETARY CONSIDERATIONS**

Heart failure can interfere with the kidney's ability to excrete sodium and water loads. Therefore dietary sodium restriction is recommended to help control fluid accumulation and reduce necessary drug therapy. Chloride restriction also appears important. However, very low salt intake can increase rennin-angiotension system activation. It is unclear whether a reduced-salt diet is necessary before overt CHF develops, but refraining from feeding the patient high-salt table scraps or treats would appear prudent. High-salt foods include processed meats; liver and kidney; canned fish; cheese, margarine, or butter; canned vegetables; breads; potato chips, pretzels, and other processed snack foods; and dog treats such as rawhide and biscuits.

Moderate salt restriction is advised when clinical heart failure develops. This represents a sodium intake of about 30 mg/kg/day (about 0.06% sodium for canned food or 210 to 240 mg/100 g of dry food). Diets for senior animals or those with renal disease usually provide this level of salt. Prescription cardiac diets usually have greater sodium restriction (e.g., 13 mg sodium/kg/day, or about 90 to 100 mg sodium/100 g of dry food, or 0.025% sodium in a canned food) and can be helpful in patients with advanced heart failure. Severe sodium restriction (e.g., 7 mg/kg/day) can exacerbate NH activation and contribute to hyponatremia. A well-balanced diet and adequate caloric and protein intake are important. Recipes for homemade low-salt diets are available, but providing balanced vitamin and mineral content may be difficult. Drinking water in some areas can contain high sodium concentrations. Nonsoftened water or (where water from the public water supply contains more than 150 ppm of sodium), distilled water can be recommended to further decrease salt intake. Supplementation of specific nutrients is important in some cases (discussed in more detail later in this section).

Inappetence is common in dogs and cats with advanced heart failure. However, more calories may be needed because of increased cardiopulmonary energy consumption or stress. Malaise, increased respiratory effort, azotemia, digoxin toxicity, and adverse effects of other medications all can contribute to poor appetite. Meanwhile, poor splanchnic perfusion, bowel and pancreatic edema, and secondary intestinal lymphangiectasia may reduce nutrient absorption and promote protein loss. Hypoalbuminemia and reduced immune function may develop. Such factors, as well as renal or hepatic dysfunction, also can alter the pharmacokinetics of certain drugs.

Strategies that sometimes help improve appetite include warming the food to enhance its flavor, adding small amounts of very palatable human foods (e.g., nonsalted meats or gravy, low-sodium soup), using a salt substitute (KCl) or garlic powder, handfeeding, and providing small quantities of the diet several times a day. If a change in diet is indicated, a gradual switch improves acceptance (e.g., mixing the new with the old diet in a 1:3 ratio for several days, then 1:1 for several days, then 3:1, and finally the new diet alone).

Cardiac cachexia is the syndrome of muscle wasting and fat loss associated with some cases of chronic CHF. Loss of muscle over the spine and gluteal region is usually noted first. Weakness and fatigue are seen with loss of lean body mass; cardiac mass also can be affected. Cardiac cachexia is thought to be a predictor of poor survival, and it is associated with reduced immune function in people. The pathogenesis of cardiac cachexia involves multiple factors, including proinflammatory cytokines, TNF<sub>cc</sub>, and interleukin-1. These substances suppress appetite and promote hypercatabolism. Dietary supplementation with fish oils, which are high in omega-3 fatty acids (eicosapentaenoic [EPA] and docosahexaenoic [DHA] acids) can reduce cytokine production and may improve endothelial function, among other beneficial effects. Approximate doses of 27 mg/kg/day EPA and 18 mg/kg/day DHA produced improvement in cachexia and lower interleukin-1 levels in dogs with dilated cardiomyopathy, although there was no effect of fish oil on overall mortality (Freeman, 1998). Whether higher EPA and DHA doses would provide added benefit is not known; 30 to 40 mg/kg/ day EPA and 20 to 25 mg/kg/day DHA orally have been recommended.

Grossly overweight pets with heart disease may benefit from a weight-reducing diet. Obesity increases metabolic demands on the heart and expands blood volume. This could increase cardiac filling and stimulate hypertrophy, increase venous pressure, and predispose the patient to arrhythmias as well as alter cardiac metabolism. Mechanical interference with respiration promotes hypoventilation; this can contribute to cor pulmonale and complicate preexisting heart disease.

## Taurine

Taurine is an essential nutrient for cats. Prolonged deficiency causes myocardial failure as well as other abnormalities (see p. 151). Most commercial and prescription cat foods are well supplemented with taurine, which has markedly reduced the prevalence of taurine-responsive dilated cardiomyopathy in cats. But taurine concentrations should be measured in cats diagnosed with dilated cardiomyopathy, because the diet of some cats may still be deficient. Taurine-deficient cats are given oral supplements of taurine (250 to 500 mg) twice daily.

Some dogs with dilated cardiomyopathy appear deficient in taurine and/or L-carnitine, most notably American Cocker Spaniels but also others (see p. 136). Dogs fed protein-restricted diets can become taurine deficient, and some develop evidence of dilated cardiomyopathy. Taurine supplementation for dogs <25 kg is 500 to 1000 mg every 8 hours; for dogs 25 to 40 kg the dose is 1 to 2 g every 8 to 12 hours. Although not all taurine-deficient American Cocker Spaniels need both taurine and L-carnitine, most appear to.

### L-carnitine

Although L-carnitine deficiency has been identified in Boxers and Doberman Pinschers with dilated cardiomyopathy, its prevalence is thought to be low and the number of affected dogs responsive to L-carnitine supplementation even lower. Nevertheless, a trial period of supplementation (at a higher dosage) may be worthwhile. After at least 4 months, reevalu-

ation by echocardiogram is done to assess LV functional improvement. Dogs treated with carnitine supplementation may give off a peculiar odor.

The minimum effective dose of L-carnitine is not known; it may vary with the type of deficiency, if present at all. Several dose ranges have been suggested, including 50 to 100 mg/kg every 8 to 12 hours for systemic deficiency or 200 mg/kg every 8 hours for myopathic deficiency. Others use 1 g of oral L-carnitine every 8 hours for dogs <25 kg and a dose of 2 g every 12 hours for dogs between 25 and 40 kg. About ½ teaspoonful of pure L-carnitine powder is the equivalent of 1 g. Both taurine and L-carnitine can be mixed with food for easier administration.

## Other Supplements

The role of other dietary supplements is unclear. Oxidative stress and free-radical damage probably play a role in the pathogenesis of myocardial dysfunction. Cytokines such as TNF, shown to increase in the circulation in heart failure, can promote oxidative stress. In people vitamin C supplementation has a beneficial effect on endothelial function, cardiac morbidity, and mortality. But the role of supplemental antioxidant vitamins in CHF is unclear, especially in animals. Whether coenzyme Q-10 provides any measurable benefit is controversial.

## Beta-Blockers in Patients With Heart Failure

β-blockers must be used cautiously, especially in animals with myocardial failure, because of their negative inotropic effects. An important role is in the management of certain arrhythmias, such as atrial fibrillation, and some ventricular tachyarrhythmias (see Chapter 4). Another potential role for some \( \beta \)-blockers is in modulating the processes that lead to pathologic cardiac remodeling in patients with heart failure. It is well known that certain agents, in people, can improve cardiac function, reverse pathologic ventricular remodeling, and reduce mortality with chronic therapy. Carvedilol (a third-generation β-blocker) appears to be most effective in this regard, but some second-generation β-blockers (e.g., metoprolol) also show a survival benefit. It is possible that carvedilol or metoprolol might play a similar beneficial role in dogs, especially those with dilated cardiomyopathy, but the clinical efficacy of this in dogs (and cats) is presently not

Carvedilol blocks  $\beta_1$ -,  $\beta_2$ -, and  $\alpha_1$ -adrenergic receptors but is without intrinsic sympathomimetic activity. It has antioxidant effects, reduces endothelin release, has some  $Ca^{++}$  blocking effect, and also is thought to promote vasodilation by affecting either NO or prostaglandin mechanisms. Peak plasma concentrations appear to be quite variable after oral administration. The drug is eliminated mainly through hepatic metabolism. The half-life is short (<2 hours) in dogs; an active metabolite is thought to account for the nonselective  $\beta$ -blocking effect, which lasts for 12 to 24 hours. Some experimental evidence suggests that metoprolol also may produce beneficial effects on myocardial function in dogs,

but ability to improve function and survival in clinical cases is unknown

Dogs with occult myocardial dysfunction, stable compensated CHF (e.g., no evidence of congestion for at least a week or more) caused by cardiomyopathy, or chronic mitral regurgitation that show signs of myocardial dysfunction (and compensated CHF) are likely good candidates for carvedilol (or metoprolol) therapy. There are presently no definitive guidelines. Initially, very low doses are used, along with conventional CHF therapy as indicated. β-blocker up-titration is done slowly. The dosage is increased every 1 to 2 weeks, if possible, over a 2-month period, to a target dose or as tolerated. Anecdotal experience suggests a starting dose of 0.05 to 0.1 mg/kg every 24 hours for carvedilol, with an eventual target of 0.2 to 0.3 mg/kg every 12 hours (or higher) if tolerated. An initial metoprolol dose might be 0.1 to 0.2 mg/kg/ day, with an eventual target of 1 mg/kg (if tolerated). Careful monitoring is important because CHF decompensation, bradycardia, and hypotension can occur.

## CHRONIC DIASTOLIC DYSFUNCTION

Furosemide is continued orally in patients that have developed CHF from hypertrophic cardiomyopathy and other causes of diastolic dysfunction. Gradual reduction to the lowest dosage level and frequency that are effective for controlling edema is the aim. A  $\beta$ -blocker or diltiazem has traditionally also been used, but the efficacy of this in cats with chronic CHF from hypertrophic cardiomyopathy is unclear. An ACEI in such cases is thought to be beneficial, unless it provokes hypotension, particularly in cats with dynamic LV outflow obstruction (see Chapter 8). Spironolactone can also be useful as an adjunct therapy, especially for cases with recurrent pleural effusion.

#### REEVALUATION AND MONITORING

Client education is important when managing dogs and cats with chronic heart failure. A good understanding of the pet's underlying disease, the signs of heart failure, and the purpose and potential adverse effects of each medication make early identification of complications more likely. Frequent reevaluation is important in patients with chronic heart failure because underlying diseases progress and complications often develop. The time frame for recheck visits may vary from weekly to every 6 months or so, depending on the severity of heart disease and the clinical stability of the patient.

Medications and dosage schedules should be reviewed at each visit, and problems with drug administration or signs of adverse effects ascertained. How well the animal has responded to medications, the diet and appetite level, activity level, and any other concerns should also be discussed. It is helpful to have owners monitor their pet's respiratory (and, if possible, heart) rate when the animal is asleep or resting at home. Resting respiratory rates for normal animals in the home environment are usually  $\leq 30$  breaths/minute. A persistent increase (of  $\geq 20\%$ ) in resting respiratory rate is often an early sign of worsening heart failure. This is because

pulmonary edema increases lung stiffness, which induces faster, more shallow respiration. Likewise, a persistent increase in resting heart rate accompanies the heightened sympathetic tone of decompensating failure.

A thorough physical examination, with emphasis on the cardiovascular system (see Chapter 1), is important at each evaluation. Depending on the patient's status, clinical tests might include a resting electrocardiogram (ECG) or ambulatory monitoring, thoracic radiographs, serum biochemistry analyses, an echocardiogram, serum digoxin concentration, or others. Periodic measurement of serum electrolyte and creatinine or BUN concentrations is recommended. Electrolyte imbalance (especially hypokalemia or hyperkalemia, hypomagnesemia, and sometimes hyponatremia) can occur from the use of diuretics, ACEIs, and salt restriction. Prolonged anorexia can contribute to hypokalemia, but potassium supplementation should not be used without documenting hypokalemia, especially when ACEIs and spironolactone are prescribed. Serum magnesium concentration does not accurately reflect total body stores; however, supplementation may be especially beneficial in animals that develop ventricular arrhythmias while receiving furosemide and digoxin.

Many factors can exacerbate the signs of heart failure, including physical exertion, infection, anemia, exogenous fluid administration (excess volume or sodium load), high-salt diet or dietary indiscretion, erratic administration of medication, inappropriate medication dosage for the level of disease, development of cardiac arrhythmias, environmental stress (e.g., heat, humidity, cold, smoke), development or worsening of concurrent extracardiac disease, and progression of underlying heart disease (e.g., ruptured chordae tendineae, left atrial tear, secondary right heart failure). Repeated episodes of acute, decompensated congestive failure that may require hospitalization and intensive diuresis are relatively common in patients with chronic progressive heart failure.

# STRATEGIES FOR REFRACTORY CONGESTIVE HEART FAILURE

Recurrent CHF while on initial therapy with furosemide and an ACEI is usually first handled by increasing the dose of furosemide and/or maximizing the ACEI dose. Pimobendan or digoxin, if not previously used, is added if inotropic support is indicated. Other ancillary therapy could include an additional diuretic or vasodilator. Spironolactone is recommended because of its action as an aldosterone antagonist and its likely cardioprotective effects. Because its benefits are thought to extend beyond additional diuresis, use of spironolactone earlier in the course of therapy may be advantageous. Some animals benefit from the addition of a thiazide diuretic as failure becomes more refractory.

Low doses of an arteriolar vasodilator to further reduce afterload (e.g., amlodipine or hydralazine) can further intensify therapy for dogs with CHF caused by mitral regurgitation or dilated cardiomyopathy. Blood pressure should be monitored. An arteriolar vasodilator is not recommended for cats with hypertrophic cardiomyopathy or dogs with fixed ventricular outflow obstruction (e.g., subaortic stenosis).

Sympathomimetic Drugs

Other Drugs

### GENERAL CONSIDERATIONS

Cardiac arrhythmias occur for many reasons. Although some arrhythmias are of no clinical consequence, others cause serious hemodynamic compromise and sudden death, especially in animals with underlying heart disease. It is important to make an accurate electrocardiographic diagnosis, as well as to consider the arrhythmia's clinical context, before deciding whether to use antiarrhythmic therapy. In people the risk of death associated with ventricular tachyarrhythmias is higher when myocardial function is impaired. Dogs with cardiomyopathy also have increased risk for sudden death, especially Doberman Pinschers and Boxers. An inherited disorder predisposing to sudden death has also been identified in young German Shepherds. On the other hand, in previously healthy animals the ventricular premature activity that occurs commonly after thoracic trauma or splenectomy (see p. 139) is usually benign and resolves without therapy.

Occasional ventricular premature complexes occur without consequence in many animals. However, arrhythmias that compromise cardiac output and coronary perfusion can lead to myocardial ischemia, deterioration of cardiac pump function, and sometimes sudden death. These arrhythmias tend to be either very rapid (e.g., sustained ventricular or supraventricular tachyarrhythmias) or very slow (e.g., advanced atrioventricular [AV] block with a slow or unstable ventricular escape rhythm). Sometimes, however, a lethal arrhythmia such as ventricular fibrillation (VF) occurs without antecedent sustained arrhythmia. Rapid sustained tachycardia of either supraventricular or ventricular origin reduces cardiac output acutely and eventually leads to myocardial dysfunction and congestive heart failure (CHF).

### **DEVELOPMENT OF ARRHYTHMIAS**

Multiple factors underlie disturbances in cardiac rhythm. Abnormalities of conduction or automaticity caused by cardiac structural or pathophysiologic remodeling can predispose to arrhythmias, even in the absence of overt cardiac disease. Genetic factors and environmental stresses contribute to this. However, additional triggering (e.g., premature stimulus or abrupt change in heart rate) and/or modulating factors (e.g., changes in autonomic tone, circulating catecholamines, ischemia, or electrolyte disturbances) are thought to be necessary to provoke and sustain a rhythm disturbance. For example, episodes of anger or aggressive behavior have been linked to increased susceptibility to ischemic arrhythmias and sudden arrhythmic death in both dogs and people. Various stresses that lead to cardiac remodeling changes also may play a role in the development of arrhythmias. Remodeling can involve myocyte hypertrophy, changes in the structure or function of ion channels, tissue fibrosis, or the activity of the autonomic nervous system (see Chapter 3). Although some of these changes act as beneficial compensatory mechanisms in the short term, they can have harmful and arrhythmogenic long-term effects. It is thought that if such underlying arrhythmogenic modulators could be controlled, arrhythmias would be lessened. Such modulators include catecholamines, free radicals, angiotensin II, cytokines, and nitric oxide (NO). The higher survival in human patients with heart failure treated with angiotensin converting enzyme (ACE) inhibitors, spironolactone, and/or some  $\beta$ -blockers supports this approach. There is similar evidence for ACE inhibitors in dogs with dilated cardiomyopathy and reason to suspect that other therapies might be beneficial as well.

# APPROACH TO ARRHYTHMIA MANAGEMENT

If antiarrhythmic drug therapy is considered, its goals should be defined. An immediate goal is to restore hemodynamic stability. Although ideal goals include conversion to sinus rhythm, correction of underlying cause, and prevention of further arrhythmia and sudden death, suppression of all abnormal beats is generally not a realistic goal. Successful therapy may mean sufficient reduction in frequency (e.g., by ≥70-80%) or repetitive rate of ectopic beats to promote normal hemodynamics and eliminate clinical signs. However, even with apparently complete conversion to sinus rhythm, the risk of sudden death from a lethal arrhythmia may remain.

Various arrhythmias and their ECG characteristics are described in Chapter 2. This section provides a general approach to managing cardiac rhythm disturbances. Nevertheless, much remains to be learned about effective arrhythmia management and the prevention of sudden death.

- 1. Record and interpret an ECG (Box 4-1); identify and define any arrhythmia. An extended ECG recording period may be needed (e.g., Holter monitor or prolonged in-hospital monitoring).
- 2. Evaluate the whole patient, including history, physical exam findings, and clinical/laboratory test results. Are signs of hemodynamic impairment evident (e.g., episodic weakness, syncope, signs of congestive heart failure)? Are other signs of cardiac disease present (e.g., heart murmur, cardiomegaly)? Are there additional abnormalities (e.g., fever, abnormal blood chemistry values, respiratory or other extracardiac disease, trauma)? Is the animal receiving any medications? Correct what can be corrected.
- 3. Decide whether to use antiarrhythmic drug therapy. Consider signalment, history, clinical signs, and underlying disease as well as the potential benefits/risks of the drug(s) under consideration.
- If an antiarrhythmic drug is to be used, define the goals of therapy for this patient.
- 5. Initiate treatment and determine drug effectiveness. Adjust dose or try alternate agents, if needed.
- Monitor patient status. Assess arrhythmia control (consider repeated Holter monitoring), manage underlying disease(s), and watch for adverse drug effects and other complications.

# DIAGNOSIS AND MANAGEMENT OF COMMON ARRHYTHMIAS

Cardiac arrhythmias in a given animal often occur inconsistently and are influenced by drug therapy, prevailing auto-

BOX 4-1

#### **ECG Interpretation Guide**

- Determine the heart rate. Is it too fast, too slow, or normal?
- 2. Is the rhythm regular or irregular?
- Is sinus rhythm present (with or without other abnormalities), or are there no consistent P-QRS-T relationships?
- 4. Are all P waves followed by a QRS and all QRS complexes preceded by a P wave?
- 5. If premature (early) complexes are present, do they look the same as sinus QRS complexes (implying atrial or junctional [supraventricular] origin), or are they wide and of different configuration than sinus complexes (implying a ventricular origin or possibly abnormal ventricular conduction of a supraventricular complex)?
- 6. Are premature QRS complexes preceded by an abnormal P wave (suggesting atrial origin)?
- 7. Are there baseline undulations instead of clear and consistent P waves, with a rapid, irregular QRS occurrence (compatible with atrial fibrillation)?
- 8. Are there long pauses in the underlying rhythm before an abnormal complex occurs (escape beat)?
- 9. Is an intermittent AV conduction disturbance present?
- 10. Is there a lack of consistent temporal relationship between P waves and QRS complexes, with a slow and regular QRS occurrence (implying complete AV block with escape rhythm)?
- 11. For sinus and supraventricular complexes, is the mean electrical axis normal?
- 12. Are all measurements and waveform durations within normal limits?

See Chapter 2 for more specific information.

nomic tone, baroreceptor reflexes, and variations in heart rate. Treatment decisions are based on consideration of the origin (supraventricular or ventricular), timing (premature or escape), and severity of the rhythm disturbance, as well as the clinical context. Accurate ECG interpretation is important. Although a routine (resting) ECG documents arrhythmias present during the recording period, it provides only a glimpse of the cardiac rhythms occurring over time. Because marked variation in frequency and severity of arrhythmias may occur over time, potentially critical arrhythmias are easily missed. For this reason, Holter monitoring or other forms of extended ECG acquisition are useful in assessing the severity and frequency of arrhythmias and monitoring treatment efficacy. Some rhythm abnormalities do not require therapy, whereas others demand immediate aggressive treatment. Close patient monitoring is especially important in patients with more serious arrhythmias.

Supraventricular tachyarrhythmias occur from various mechanisms, including reentry involving the AV node, accessory pathways, or sinoatrial (SA) node, as well as abnormal automaticity within atrial or junctional tissue. Many patients have atrial enlargement. Common underlying heart diseases

BOX 4-2

### Factors Predisposing to Arrhythmias

## Atrial Arrhythmias

#### Cardiac

Mitral or tricuspid insufficiency Dilated cardiomyopathy Hypertrophic cardiomyopathy Restrictive cardiomyopathy

Cardiac neoplasia

Congenital malformation
Accessory AV nodal bypass tract(s)

Myocardial fibrosis High sympathetic tone

İschemia

Intractrial catheter placement

#### Extracardiac

Catecholamines Electrolyte imbalances Digoxin toxicity

Other drugs (anesthetic agents, bronchodilators)

Acidosis/alkalosis

Hypoxia Thyrotoxicosis Severe anemia Electric shock Thoracic surgery

## Ventricular Arrhythmias

#### Cardiac

Congestive heart failure

Cardiomyopathy (especially Doberman Pinschers and

Boxers) Myocarditis Pericarditis Degenerative valvular disease with myocardial fibrosis

Ischemia

Trauma

Cardiac neoplasia Heartworm disease Congenital heart disease

Ventricular dilation

Mechanical stimulation (intracardiac catheter, pacing wire)

#### Extracardiac

Hypoxia

Electrolyte imbalances (especially K\*)

Acidosis/alkalosis Thyrotoxicosis Hypothermia Fever

Sepsis/toxemia

Trauma (thoracic or abdominal)

Gastric dilation/volvulus Splenic mass or splenectomy

Hemangiosarcoma Pulmonary disease

Uremia Pancreatitis Pheochromocytoma

Other endocrine diseases (diabetes mellitus, Addison's

disease, hypothyroidism)

High sympathetic tone (pain, anxiety, fever)

Central nervous system disease (increases in sympathetic or vagal stimulation)

Electric shock

Drugs (digoxin, sympathomimetics, anesthetics, tranquilizers, anticholinergics, antiarrhythmics)

include chronic mitral or tricuspid valve degeneration with regurgitation, dilated cardiomyopathy, congenital malformations, and cardiac neoplasia. Other factors also may predispose to atrial tachyarrhythmias (Box 4-2).

Ventricular premature contractions (VPCs) occur in association with disorders that affect cardiac tissue directly or indirectly through neurohormonal effects (see Box 4-2). For instance, disorders of the central nervous system can produce abnormal neural effects on the heart that cause ventricular or supraventricular arrhythmias (brain-heart syndrome). When VPCs are infrequent or underlying cardiac function is normal, adverse hemodynamic effects may be negligible. However, hemodynamic impairment can be severe in dogs or cats with underlying heart disease, rapid ventricular rates, or myocardial depression stemming from a systemic disease.

Factors such as underlying hypoxia, electrolyte or acidbase imbalances, and abnormal hormone concentrations (e.g., thyroid) can exacerbate arrhythmias. Therefore corfecting these is usually important for arrhythmia control. Because some drugs can provoke arrhythmias, reducing dosage or discontinuing the medication may be useful.

## **CLINICAL PRESENTATION**

Box 4-3 lists common arrhythmias according to a clinical description of the heartbeat.

# TACHYARRHYTNMIAS Rapid Irregular Rhythms

Irregular heart rhythms are common, and the ECG is important for differentiating abnormal rhythms as well as sinus arrhythmia. Pulse deficits (see p. 6) and an irregular, weak pulse with heart sounds of varying intensity and regularity may be detected on physical examination. Premature contractions interrupt ventricular filling and reduce stroke volume, sometimes to the extent that there is no ejection at all for that cycle (Fig. 4-1). Rapid atrial fibrillation (AF) and premature contractions of any origin often cause pulse deficits. Ventricular premature complexes can cause audible splitting of the heart sounds because of asynchronous ven-

Clinical Characterization of Common Heart Rate and Rhythm Disturbances

#### Fast, Irregular Rhythms

#### Slow, Regular Rhythms

Sinus bradycardia
Complete (third-degree) AV block with ventricular escape
rhythm
Atrial standstill with ventricular escape rhythm

tricular activation. Ventricular and supraventricular tachycardias and AF cause more severe hemodynamic compromise than do isolated premature contractions, especially in patients with underlying heart disease.

### Rapid Regular Rhythms

Rapid regular rhythms include sinus tachycardia, sustained supraventricular tachycardia (SVT), and sustained ventricular tachycardia. Sinus tachycardia is caused by high sympathetic tone or drug-induced vagal blockade. Underlying causes include anxiety, pain, fever, thyrotoxicosis, heart failure, hypotension, shock, the ingestion of stimulants or toxins (e.g., chocolate, caffeine), or drugs (e.g., catecholamines, anticholinergics, theophylline, and related agents). The heart rate in dogs and cats with sinus tachycardia is usually <300 beats/min, although it can be higher in those with thyrotoxicosis or in those that have ingested exogenous stimulants or drugs (particularly cats). Alleviation of the underlying cause and intravenous (IV) administration of fluids to reverse hypotension (in animals without edema) should cause the sympathetic tone and sinus rate to decrease.

SVT of varying causes can be difficult to differentiate from sinus tachycardia. The heart rate in patients with SVT is often >300 beats/min, but it is rare for the sinus rate to be this rapid. Patients with SVTs, such as sinus tachycardia, usually have a normal QRS configuration (narrow and upright in lead II). However, if an intraventricular conduc-

tion disturbance is present, SVT may resemble ventricular tachycardia. A vagal maneuver can be useful in differentiating among narrow QRS complex tachycardias.

Sustained, rapid arrhythmias lead to decrease in cardiac output, arterial blood pressure, and coronary perfusion. CHF eventually may result. Signs of poor cardiac output and hypotension include weakness, depression, pallor, prolonged capillary refill time, exercise intolerance, syncope, dyspnea, prerenal azotemia, worsening rhythm disturbances, and sometimes altered mentation, seizure activity, and sudden death.

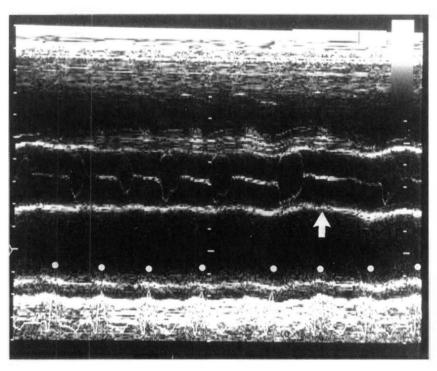

## Supraventricular Tachyarrhythmias

Occasional premature beats do not require specific therapy. Factors that predispose to these arrhythmias should be minimized as much as possible (e.g., discontinue or reduce dosage of suspected drugs, manage heart failure if present, and treat metabolic or endocrine abnormalities).

Oral therapy for frequent supraventricular premature beats and paroxysmal tachycardia. Initial oral therapy for frequent atrial premature complexes (APCs) or paroxysmal SVT usually involves either digoxin, diltiazem, a β-blocker, or a combination of these. Digoxin (see Table 3-3) is the initial oral drug of choice in dogs with heart failure and cats with dilated cardiomyopathy (Fig. 4-2). A β-blocker or the calcium entry blocker diltiazem may be added to the regimen if the arrhythmia is not controlled with digoxin, along with other therapy (including an ACE inhibitor) indicated for heart failure. Cats with hypertrophic cardiomyopathy or hyperthyroidism are usually treated with a β-blocker such as atenolol, although diltiazem is an alternative. Refractory intermittent supraventricular tachyarrhythmias may respond to amiodarone, sotalol, procainamide, quinidine, or a class IC agent.

### Acute therapy for supraventricular tachycardia.

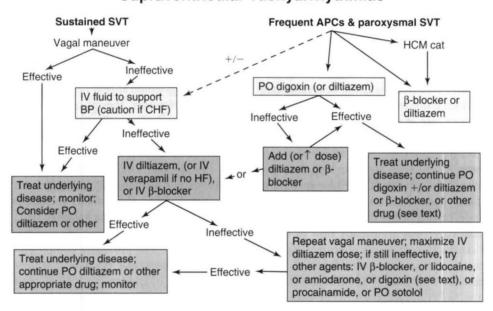

More aggressive therapy is warranted for rapid and persistent supraventricular tachyarrhythmias, especially in the face of hemodynamic impairment. A vagal maneuver can be tried first (discussed in more detail in the following section). IV access is secured, and fluids are administered to maintain blood pressure and enhance endogenous vagal tone. However, patients with known or suspected heart failure should receive a small volume slowly, if at all. If a vagal maneuver does not terminate the arrhythmia, diltiazem IV (or oral loading) is often chosen first because of its lesser negative inotropic effects. Although verapamil (IV) is equally effective against SVTs, it is not recommended for dogs with myocardial dysfunction or heart failure because of its greater negative inotropic effects. A slowly administered IV β-blocker (e.g., propranolol, esmolol) is an alternative therapy but also has negative inotropic effects in animals with high underlying sympathetic tone. Some cases of reentrant SVT or automatic atrial tachycardia respond to IV lidocaine. IV digoxin also may be tried, but this has been less effective than the calcium channel blockers. Digoxin has a slower onset of action, and although it increases vagal tone, IV administration can also increase central sympathetic output. IV amiodarone is an

#### FIG 4-1

M-mode echocardiogram at the aortic root level in a Doberman Pinscher with atrial fibrillation and dilated cardiomyopathy. Pulse deficits and variable-intensity pulses occurred secondary to the variable (or absent) aortic valve opening caused by the arrhythmia and illustrated in this echocardiogram. The motion of two aortic valve leaflets is seen within the parallel aortic root echocardiograms. Most cycles are associated with variable and poor stroke volume and with abbreviated aortic valve opening, but there is no opening at all after the sixth electrocardiogram complex from the left (arrow). R waves are indicated by white dots.

## Supraventricular Tachyarrhythmias

#### FIG 4-2

A therapeutic approach to supraventricular tachyarrhythmias. See Table 4-2 for drug doses and text for more information. APCs, Atrial premature contractions; BP, blood pressure; CHF, congestive heart failure; HCM, hypertrophic cardiomyopathy; HF, heart failure or myocardial dysfunction; SVT, supraventricular tachycardia.

alternative agent in refractory cases. Sotalol or a class IA or IC drug might be tried if the arrhythmia is unremitting. Adenosine appears to be ineffective in dogs for terminating SVTs. Further cardiac diagnostic tests are indicated once conversion is achieved or the ventricular rate has decreased to <200 beats/min. Once the rhythm is better controlled, oral diltiazem, digoxin, amiodarone, or  $\beta$ -blockers are options for chronic therapy; combinations of these agents can be used.

Paroxysmal AV reciprocating tachycardia is a reentrant tachycardia involving an accessory pathway and the AV node (see p. 27). It is interrupted by slowing conduction or prolonging the refractory period of either or both tissues. A vagal maneuver may slow AV conduction enough to terminate the rhythm. Diltiazem and β-blockers slow AV conduction and increase refractoriness. Another approach is IV amiodarone or procainamide. Digoxin slows AV conduction but has variable effects on the accessory pathway; its use is usually discouraged in people with preexcitation syndromes. Procainamide and quinidine may prevent AV reciprocating tachycardia because they lengthen the refractory period of the accessory pathway. High-dose procainamide, with or without a β-blocker or diltiazem, has been successful in preventing the recurrence of tachycardia in some cases. Intracardiac electrophysiologic mapping with radiofrequency catheter ablation of accessory pathways has been used successfully to abolish refractory SVT associated with preexcitation in dogs, although this technique is not widely available yet.

Atrial tachycardia caused by a persistent automatic ectopic focus may be particularly difficult to suppress. When the antiarrhythmic strategies outlined in the preceding paragraphs are unsuccessful, the goal of therapy shifts to ventricular rate control. By prolonging AV conduction time and refractoriness, fewer atrial impulses are then conducted and ventricular rate is slowed (and usually irregular). Therapy with combinations of diltiazem or a  $\beta$ -blocker and digoxin, sotalol, or amiodarone can be effective. The animal with persistent automatic atrial tachycardia could be a candidate for intracardiac electrophysiologic mapping and catheter ablation when such tools are available. Alternatively, heart rate control could be achieved by AV node ablation with permanent pacemaker implantation.

**Vogal maneuver.** A vagal maneuver can help the clinician differentiate among tachycardias caused by an ectopic automatic focus, those dependent on a reentrant circuit involving the AV node, or excessively rapid sinus node activation. The vagal maneuver may transiently slow or intermittently block AV conduction, exposing abnormal atrial P' waves, and allow an ectopic atrial focus to be identified. Vagal maneuvers can terminate reentrant SVTs involving the AV node by interrupting the reentrant circuit. The maneuver tends to temporarily slow the rate of sinus tachycardia.

Vagal maneuvers are performed by massaging the area over the carotid sinuses (below the mandible in the jugular furrows) or by applying firm bilateral ocular pressure for 15 to 20 seconds. Although initial attempts are often unsuccessful, repeating the vagal maneuver after antiarrhythmic drug injection may be useful.  $\beta$ -blockers, Ca<sup>+-</sup> entry-blockers, digoxin, and other agents can increase the effectiveness of vagal maneuvers. The vagal maneuver can be further potentiated in dogs by administering intramuscular (IM) morphine sulfate (0.2 mg/kg) or IV edrophonium chloride (1 to 4 mg; atropine and an endotracheal tube should be readily available).

## Ventricular Tachyarrhythmias

Occasional VPCs in an otherwise asymptomatic animal should not be treated. Moderately frequent single VPCs of uniform configuration may not require antiarrhythmic drug treatment either, especially if underlying heart function is normal. Nevertheless, guidelines as to whether, when, and how best to treat intermittent ventricular tachyarrhythmias remain undefined. Besides being expensive, antiarrhythmic drugs can have serious adverse effects, can provoke additional arrhythmias (proarrhythmic effects), and may not be efficacious. Pretreatment and posttreatment 24- to 48-hour ambulatory ECG recordings showing at least a 70% to 80% reduction in arrhythmia frequency provide the best indicator of drug arrhythmia-suppression efficacy. Intermittent ECG recordings cannot truly differentiate between drug effect (or lack thereof) and the spontaneous, marked variability of arrhythmia frequency that occurs in any individual. However, in-hospital ECG recordings of 15 seconds to several minutes in duration are often the most practical attempt to monitor arrhythmias.

Several factors influence the decision to use ventricular antiarrhythmic drug therapy. These factors include the nature of the animal's underlying disease, the perceived severity of the arrhythmia, and the presence or absence of hemodynamic compromise. Diseases such as dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy in Boxers, hypertrophic cardiomyopathy, and subaortic stenosis, among others, are frequently associated with sudden death from arrhythmias. Therefore ventricular antiarrhythmic therapy would appear most urgent in animals with these diseases. However, the efficacy of a particular therapy to prolong survival as well as suppress the arrhythmia is difficult to accurately assess. Traditional guidelines for instituting ventricular antiarrhythmic therapy have been based on frequency, prematurity, and variability of the QRS configuration of the arrhythmia. Characteristics thought to imply increased electrical instability include rapid paroxysmal or sustained ventricular tachycardia (e.g., >130 beats/min), multiform (polymorphic) VPC configuration, or close coupling of VPCs to preceding complexes (R-on-T phenomenon). However, clear evidence that these guidelines predict greater risk of sudden death in all patients is lacking. It is probably more important to consider the animal's underlying heart disease and whether the arrhythmia is causing signs of hypotension or low cardiac output. Animals that are hemodynamically unstable or have a disease associated with sudden cardiac death are treated earlier and more aggressively.

Acute therapy for ventricular tachycardia. Sustained ventricular tachycardia is treated aggressively because it can result in marked decreases in arterial blood pressure, especially at faster rates. Lidocaine (IV) is usually the first-choice drug for controlling serious ventricular tachyarrhythmias in hospitalized dogs. It is effective against arrhythmias of several underlying mechanisms and has minimal adverse hemodynamic effects. Because the effects of IV boluses last only about 10 to 15 minutes, a constant rate infusion (CRI) is warranted if the drug is effective. Small supplemental IV boluses can be given in addition to the CRI to maintain therapeutic drug concentrations until a steady state is achieved. IV infusion can be continued for several days, if needed. If lidocaine is ineffective after maximal recommended doses, several other strategies can be tried (Fig. 4-3).

IV amiodarone or oral mexiletine or sotalol can be more effective in some cases. With IV amiodarone, slow injection of conservative doses and blood pressure monitoring are recommended because marked hypotension can occur. Alternatively, procainamide (given intravenously, intramuscularly, or orally) or quinidine (given intramuscularly or orally) can be tried next. Effects of a single IM or oral loading dose of either drug should occur within 2 hours. If this is effective, lower doses can be given every 4 to 6 hours intramuscularly or orally. If ineffective, the dose can be increased or another antiarrhythmic drug chosen. Quinidine is not given intravenously because of its hypotensive effects. This drug is also not recommended in patients on digoxin or that have prolonged QT intervals. If the arrhythmia has not been controlled, a β-blocker can be added.

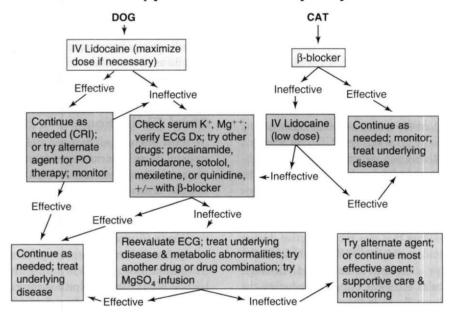

Cats with frequent ventricular tachyarrhythmias are usually given a  $\beta$ -blocker first. Alternatively, low doses of lidocaine can be administered. However, cats, especially if not anesthetized, can be quite sensitive to the neurotoxic effects of this drug. Procainamide or sotalol can also be used.

Digoxin is not used specifically for treating ventricular tachyarrhythmias, although it may be indicated for patients with concurrent heart failure and supraventricular arrhythmias. Digoxin can also predispose to the development of ventricular arrhythmias. Another antiarrhythmic drug may be necessary in animals with preexisting frequent or repetitive VPCs. Phenytoin is used only in dogs for digitalis-induced ventricular tachyarrhythmias that are refractory to lidocaine. Ancillary KCl supplementation (if serum  $K^+ \leq 4~mEq/L$ ) with or without MgSO $_4$  can increase antiarrhythmic efficacy.

Close ECG monitoring and further diagnostic testing should follow initial therapy. Total suppression of persistent ventricular tachyarrhythmias is not expected. The patient's clinical status, the underlying disease(s), the success of the drug in suppressing the arrhythmia, and the drug dosage (e.g., whether it could be increased) all influence the decision whether to continue or discontinue current treatment or to use a different drug. Clinical status and results of diagnostic testing also guide decisions about chronic oral therapy.

If the ventricular tachyarrhythmia appears refractory to initial treatment attempts, one or more of the following considerations may be helpful:

## Acute Therapy - Ventricular Tachyarrhythmias

**FIG 4-3** A therapeutic approach to ventricular tachyarrhythmias. See Table 4-2 for drug doses and text for more information. *CRI*, Constant-rate infusion; *Dx*, diagnosis; *ECG*, electrocardiogram.

- Reevaluate the ECG—could the rhythm have been incorrectly diagnosed initially? For example, SVT with an intraventricular conduction disturbance can mimic ventricular tachycardia. In such cases, IV diltiazem is usually more effective than lidocaine.
- 2. Reevaluate the serum K<sup>+</sup> (and Mg<sup>++</sup>) concentration. Hypokalemia reduces the efficacy of class I antiarrhythmic drugs (e.g., lidocaine, procainamide, quinidine) and can predispose to the development of arrhythmias. If the serum K<sup>+</sup> concentration is <3 mEq/L, KCl can be infused at 0.5 mEq/kg/hr; for serum K<sup>+</sup> between 3 to 3.5 mEq/L, KCl can be infused at 0.25 mEq/kg/hr. A serum K<sup>+</sup> concentration in the high normal range is the goal. If the serum Mg<sup>++</sup> concentration is <1.0 mg/dl, MgSO<sub>4</sub> or MgCl<sub>2</sub>, diluted in D<sub>5</sub>W, can be administered at 0.75 to 1.0 mEq/kg/day by CRI.
- 3. Maximize the dose of the conventional antiarrhythmic drug having the greatest effect.
- 4. Try amiodarone (IV), sotalol (oral), or a β-blocker in conjunction with a class I drug (e.g., propranolol, esmolol, or atenolol with procainamide or lidocaine) or a class IA drug with a IB drug (e.g., procainamide with lidocaine or mexiletine).
- 5. Consider the possibility that the drug therapy is exacerbating the rhythm disturbance (a proarrhythmic effect). Polymorphous ventricular tachycardia (torsades de pointes) has been associated with quinidine, procainamide, and other drug toxicities.
- 6. MgSO<sub>4</sub> may be effective in animals with ventricular tachyarrhythmias associated with digoxin toxicity or with suspected polymorphous ventricular tachycardia (torsades de pointes). A slowly administered IV bolus of 25 to 40 mg/kg, diluted in D₅W, followed by an infusion of the same dose over 12 to 24 hours, has been suggested. Given that MgSO<sub>4</sub> contains 8.13 mEq magnesium per gram, a similar magnesium dose is provided by calculating 0.15 to 0.3 mEq/kg.
- 7. If the animal is tolerating the arrhythmia well, continue supportive care, correct other abnormalities as possible, and continue cardiovascular monitoring alone or with the most effective antiarrhythmic drug.
- 8. Direct current (DC) cardioversion or ventricular pacing may be available at a referral center; ECG-synchronized equipment and anesthesia or sedation are required. High-energy, nonsynchronized shock (defibrillation) can be used for rapid polymorphic ventricular tachycardia or flutter degenerating into fibrillation.

Chronic oral therapy for ventricular tachyarrhythmias. The same drug that was most effective during acute therapy, or a similar one, is often continued orally when long-term therapy is thought to be needed. Although suppression of ventricular ectopy is one aim, reducing the risk of sudden arrhythmic death is the real issue for longterm therapy. Whereas the Class IB drugs (lidocaine and mexiletine) appear to raise the fibrillation threshold more than the Class IA agents (procainamide and quinidine), Class III agents appear to have much greater antifibrillatory effects than the Class I drugs. Concurrent disease should be treated if possible. It is likely that animals with arrhythmias associated with underlying heart disease also benefit from the use of  $\beta$ -blockers, ACE inhibitors, and some other therapies, as do people. However,  $\beta$ -blockers alone do not appear effective in suppressing ventricular tachyarrhythmias in Doberman Pinschers with cardiomyopathy.

Several strategies are available for long-term oral therapy of patients with ventricular tachyarrhythmias:

- A Class I agent alone: sustained-release procainamide, mexiletine, (or possibly tocainide); occasionally a class IA and IB drug are used together. However, Class I drugs provide questionable protection from VF.
- 2. A Class I agent combined with a β-blocker (Class II) agent: sustained release procainamide or mexiletine and atenolol or propranolol. β-Blockers can be useful for both ventricular and supraventricular arrhythmias that are provoked by sympathetic stimulation or release of catecholamines. β-Blockers may confer some protection against VF.
- A Class III agent: sotalol or amiodarone. These drugs may provide greater antifibrillatory protection, but they also have potentially serious adverse effects.

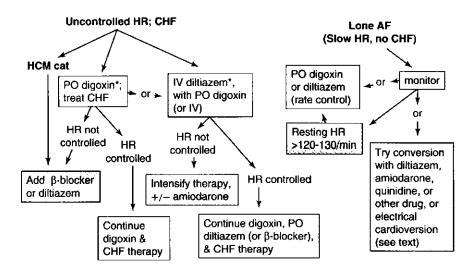

Presently, the three most favored options are sotalol; amiodarone; or mexiletine or sustained-release procainamide with atenolol, because they are likely to provide a greater antifibrillatory effect.

Frequent reevaluation is important for patients on long-term antiarrhythmic therapy (for any rhythm disturbance). Patients' owners can be shown how to use a stethoscope or palpate the chest wall to count the number of "skipped" beats per minute at home; this may yield an approximation of the frequency of arrhythmic events (either single or paroxysms). However, continuous 24- to 48-hour ambulatory ECG recordings are more accurate. The decision to continue or discontinue successful antiarrhythmic therapy is also based on consideration of the clinical situation and any underlying cardiac disease.

#### Atrial Fibrillation

AF most often develops when there is marked atrial enlargement. It is a serious arrhythmia, especially when the ventricular response rate is high. Predisposing conditions include dilated cardiomyopathy, chronic degenerative AV valve disease, congenital malformations that cause atrial enlargement, and hypertrophic or restrictive cardiomyopathy in cats. Clinical heart failure is common in these animals. AF is characterized by an irregular and usually rapid ventricular response rate. When little time is available for ventricular filling, stroke volume is compromised. Furthermore, atrial contraction (the "atrial kick"), which is especially important to ventricular filling at faster heart rates, is lost. Cardiac output tends to decrease considerably when AF develops; poor myocardial function exacerbates this decrease.

## **Atrial Fibrillation**

<sup>\*</sup> See text for precautions in animals with pre-excitation that develop AF

**FIG 4-4**A therapeutic approach to atrial fibrillation. See Table 4-2 for drug doses and text for more information. *AF*, atrial fibrillation; *CHF*, congestive heart failure; *HCM*, hypertrophic cardiomyopathy; *HR*, heart rate.

Long-lasting conversion to sinus rhythm is rare in the face of marked underlying cardiac disease, even after successful electrical cardioversion. Therefore treatment in most cases is directed at reducing the ventricular response rate by slowing AV conduction (Fig. 4-4). A slower heart rate allows more time for ventricular filling and lessens the relative importance of atrial contraction. In-hospital heart rates <150 (or 180 in cats) beats/min are desirable. Heart rate should be documented by ECG; counting the ventricular rate by auscultation or palpation is often highly inaccurate. Resting heart rate at home, which can be monitored by the owner, is a better indicator of drug effectiveness. Heart rates of 70 to 120 beats/min in dogs and 80 to 140 beats/min in cats are probably acceptable.

Therapy for atrial fibrillation. The oral drug of first choice for most dogs with AF is digoxin (see Table 3-3). If the heart rate exceeds 200 to 220 beats/min at rest, twice the eventual oral maintenance dosage can be given for 1 to 2 days. When more immediate heart rate reduction is indicated, IV diltiazem is recommended. This has less negative inotropic effect than verapamil or an IV  $\beta$ -blocker, although esmolol could be cautiously tried because of its short half-life. If dobutamine or dopamine infusion is needed to support myocardial function (see p. 60 and Box 3-1), IV diltiazem or an IV loading dose of digoxin (cautiously) can be used, but a  $\beta$ -blocker should be avoided.

Digoxin alone does not adequately reduce the heart rate in many animals. Increases in sympathetic tone from CHF, exercise, or excitement can override the vagal effect of digoxin on AV conduction. Either a  $\beta$ -blocker or diltiazem can be added and titrated upward as needed to further slow AV

conduction and ventricular rate. Because of their potential to depress myocardial function, the agent chosen is usually added 1 to 2 days after starting oral digoxin in most patients with reduced myocardial contractility. Amiodarone can be added (or substituted) for additional rate control. An occasional dog will revert to sinus rhythm in response to diltiazem or amiodarone therapy. Digoxin is not used in cats with hypertrophic cardiomyopathy that develop AF; a β-blocker or diltiazem is used instead.

When AF develops in patients that also have ventricular preexcitation, AV nodal blocking drugs ( $Ca^{++}$  blockers, digoxin, and possibly  $\beta$ -blockers) should not be used because they can paradoxically increase the ventricular response rate. Amiodarone is recommended in these cases. Sotalol or procainamide can also be used.

Electrical cardioversion of AF has been of limited success in animals; most revert to AF. Newer methods, including biphasic current delivery combined with amiodarone (or other drug) therapy, may be more successful. Nevertheless, experience with AF in people suggests that heart rate control provides similar survival benefit (and fewer adverse effects) than conversion to sinus rhythm.

## Lone atrial fibrillation

AF sometimes develops in large or giant-breed dogs without cardiomegaly or other evidence of structural heart disease. This can occur transiently, usually in association with trauma or surgery. AF with a slow ventricular response rate can also be an incidental finding in such dogs. This is known as "lone AF". Acute AF without signs of heart disease or failure may convert to sinus rhythm spontaneously or in response to

drug therapy, such as with diltiazem (e.g. PO for ~3 days), amiodarone, or possibly sotalol or other Class III or IC agents. Acute onset AF associated with high vagal tone may convert with IV lidocaine. Quinidine PO or IM has been used for acute AF conversion in large dogs without signs of heart disease; but adverse effects can include increased ventricular response rate from the drug's vagolytic effects, ataxia, and most seriously, seizures or polymorphic ventricular tachycardia. If effective, the drug is discontinued after sinus rhythm is achieved. Dogs that do not convert to sinus rhythm are either given digoxin or continued on diltiazem for rate control. Alternatively, if the ventricular rate is consistently low at rest, dogs can be monitored periodically without therapy; but rapid heart rates still are likely with exercise or excitement.

# BRADYARRHYTHMIAS Sinus Bradycardia

Slow sinus rhythm (or arrhythmia) can be a normal finding, especially in athletic dogs. Sinus bradycardia has also been associated with the administration of various drugs (e.g., xylazine, thorazine tranquilizers, some anesthetic agents, medetomidine, digoxin, calcium entry blockers,  $\beta$ -blockers, parasympathomimetic drugs), trauma or diseases of the central nervous system, organic disease of the sinus node, hypothermia, hyperkalemia, and hypothyroidism, among other disorders. Conditions that increase vagal tone (e.g., respiratory or gastrointestinal tract disease or a mass involving the vagosympathetic trunk) may induce sinus bradycardia. Chronic pulmonary disease often is associated with pronounced respiratory sinus arrhythmia.

In most cases of sinus bradycardia, the heart rate increases in response to exercise or atropine administration, and no clinical signs are associated with the slow heart rate. Symptomatic dogs usually have a heart rate slower than 50 beats/min and/or pronounced underlying disease. Because sinus bradycardia and sinus bradyarrhythmia are extremely rare in cats, a search for underlying cardiac or systemic disease (e.g., hyperkalemia) is warranted in any cat with a slow heart rate.

When sinus bradycardia is associated with signs of weakness, exercise intolerance, syncope, or worsening underlying disease, an anticholinergic (or adrenergic) agent is given (Fig. 4-5). If sinus bradycardia is the result of a drug effect, discontinuation, dosage reduction, or other therapy should be used, as appropriate (e.g., reversal of anesthesia or medetomidine, calcium salts for calcium entry blocker overdose, dopamine or atropine for  $\beta$ -blocker toxicity). If there is inadequate increase in heart rate with medical therapy, temporary or permanent pacing is indicated (see Suggested Readings).

# **Sick Sinus Syndrome**

Sick sinus syndrome is a condition of erratic sinoatrial function characterized by episodic weakness, syncope, and Stokes-Adams seizures. Older female Miniature Schnauzers and West Highland White Terriers are commonly affected in

# Symptomatic Bradyarrhythmia

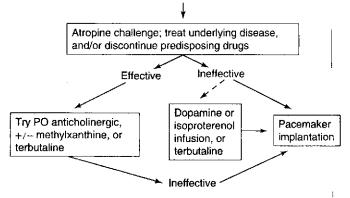

FIG 4-5
A therapeutic approach to managing symptomatic bradyar-rhythmias. See Box 3-1 and Table 4-2 and text for more information.

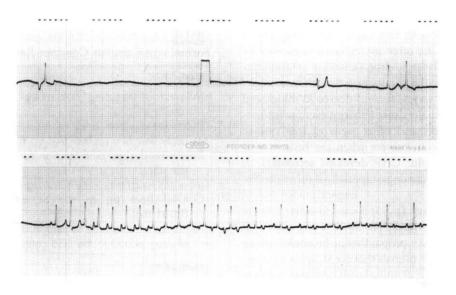

different regions, but the syndrome is also seen in Dachshunds, Cocker Spaniels, Pugs, and mixed-breed dogs. Affected dogs have episodes of marked sinus bradycardia with sinus arrest (or sinoatrial block). Sick sinus syndrome is extremely rare in cats.

Abnormalities of the AV conduction system may coexist, causing the activity of subsidiary pacemakers to be depressed and leading to prolonged periods of asystole. Some affected dogs also have paroxysmal SVTs, prompting the name *bradycardia-tachycardia syndrome* (Fig. 4-6). Premature complexes may be followed by long pauses before sinus node activity resumes, indicating a prolonged sinus node recovery time. Intermittent periods of accelerated junctional rhythms and variable junctional or ventricular escape rhythms may also occur.

Clinical signs can result from bradycardia and sinus arrest, paroxysmal tachycardia, or both. Signs can mimic seizures stemming from neurologic or metabolic disorders. Concurrent degenerative AV valve disease is also often present. Some dogs have evidence of CHF, usually secondary to AV valve regurgitation, although the arrhythmias may be a complicating factor.

ECG abnormalities are frequently pronounced in dogs with long-standing sick sinus syndrome. Nevertheless, some dogs have one or more normal resting ECGs. Prolonged visual ECG monitoring or 24-hour ambulatory ECG can help establish a definitive diagnosis. An atropine challenge test is done in dogs with persistent bradycardia (see p. 93). The normal response is an increase in the heart rate of 150% or to >130 to 150 beats/min. Dogs with sick sinus syndrome generally have a subnormal response.

Therapy with an anticholinergic agent, methylxanthine bronchodilator, or terbutaline given orally may temporarily help some animals that have a positive response to atropine challenge. However, anticholinergic or sympathomimetic drugs used to accelerate the sinus rate can also exacerbate tachyarrhythmias. Conversely, drugs used to suppress these supraventricular tachyarrhythmias can magnify the brady-

#### FIG 4-6

Continuous electrocardiogram from an 11-year-old female Miniature Schnauzer with sick sinus syndrome, illustrating a combination of bradycardia and tachycardia. The top portion shows persistent sinus arrest with three different escape complexes, followed by an atrial premature complex. There is a 1-mV calibration mark in the middle of the top strip. The bradycardia is interrupted by a run of atrial tachycardia at a rate of 250 beats/min, with 1:1 atrioventricular conduction initially; but starting in the middle of the bottom strip, every other P' wave is blocked (2:1 atrioventricular conduction).

cardia, although digoxin or diltiazem is helpful in some dogs if used cautiously. Sick sinus syndrome with frequent or severe clinical signs is best managed by permanent artificial pacing. The Suggested Readings list includes sources of further details on pacing. Dogs that remain symptomatic because of paroxysmal SVTs can safely be given appropriate antiarrhythmic therapy once a normally functioning pacemaker is in place.

# **Atrial Standstill**

Persistent atrial standstill is a rhythm disturbance characterized by lack of effective atrial electrical activity (i.e., no P waves and a flat baseline) in which a junctional or ventricular escape rhythm controls the heart. This bradyarrhythmia is rare in dogs and extremely rare in cats; most cases have occurred in English Springer Spaniels with muscular dystrophy of the fascioscapulohumeral type, although infiltrative and inflammatory diseases of the atrial myocardium can also result in atrial standstill. Because organic disease of the atrial myocardium may also involve the ventricular myocardium, persistent atrial standstill may be a harbinger of a serious and progressive cardiac disorder.

Medical treatment for persistent atrial standstill is rarely rewarding; however, an anticholinergic drug or an infusion of dopamine or isoproterenol can sometimes temporarily accelerate the escape rhythm. If ventricular tachyarrhythmias result from this treatment, the drug should be discontinued or the dose reduced. Oral terbutaline may also have some beneficial effect. Antiarrhythmic agents are contraindicated in these animals because they may suppress the

escape focus, as well as the tachyarrhythmia. Permanent pacemaker implantation is the treatment of choice, although the prognosis is poor in dogs with concurrent ventricular myocardial dysfunction.

Hyperkalemia should be ruled out in animals without P waves. The apparent lack of atrial electrical and mechanical activity ("silent atrium") caused by hyperkalemia will resolve with treatment. Sinus node activity (and P waves) become evident as the serum K<sup>+</sup> concentration returns to normal.

# **Atrioventricular Conduction Block**

Second-degree, or intermittent, AV block usually causes an irregular heartbeat. In contrast, the ventricular escape rhythm that occurs with a third-degree, or complete, AV block is regular, although premature contractions or shifts in the escape focus may cause some irregularities. AV conduction disturbances may result from therapy with certain drugs (e.g., agonists, opioids, digoxin), high vagal tone, or organic disease of the AV node. Diseases that have been associated with AV conduction disturbances include bacterial endocarditis (of the aortic valve), hypertrophic cardiomyopathy, infiltrative myocardial disease, and myocarditis. Idiopathic heart block may occur in middle-aged to older dogs; congenital third-degree heart block has also been seen in dogs. Symptomatic heart block is less common in cats, but evidence of any AV conduction disturbance should prompt further diagnostic evaluation. Most cases have been associated with hypertrophic cardiomyopathy. Heart block is occasionally found in old cats without detectable organic heart disease.

Type I second-degree AV block and first-degree AV block are frequently associated with high vagal tone or drug effects in dogs. These animals are often asymptomatic; exercise or injection of an anticholinergic drug (atropine or glycopyrrolate) usually abolishes the conduction disturbance. Highgrade (many blocked P waves) second-degree AV block and complete heart block usually cause lethargy, exercise intolerance, weakness, syncope, and other signs of low cardiac output. These signs become severe when the heart rate is consistently <40 beats/min. CHF develops secondary to chronic bradycardia in some dogs, especially if other cardiac disease is present.

An atropine challenge test (p. 93) is used to determine the degree of vagal influence on the AV block. Long-term oral anticholinergic therapy (e.g., propantheline bromide) can be attempted in symptomatic animals that are atropine-responsive (see Fig. 4-5). Atropine or subsequent oral anticholinergic therapy is often ineffective, however, so artificial pacing is usually indicated. An emergency infusion of dopamine (see Box 3-1) or isoproterenol may increase the ventricular escape rate in animals with high-grade second- or thirddegree block, although ventricular tachyarrhythmias may also be provoked. Oral isoproterenol is usually ineffective. A thorough cardiac workup is indicated before permanent artificial pacemaker implantation because some underlying diseases (e.g., myocardial disease, endocarditis) are associated with a poor prognosis, even after pacing. Temporary transvenous pacing is sometimes used for 1 to 2 days to assess the animal's response to a normal heart rate before permanent pacemaker surgery is performed.

# ANTIARRHYTHMIC AGENTS

Antiarrhythmic drugs can act by slowing the rate of a tachycardia, terminating a reentrant arrhythmia, or preventing abnormal impulse formation or conduction. These effects occur through modulation of tissue electrophysiologic properties and/or autonomic nervous system effects. The traditional (Vaughan-Williams) antiarrhythmic drugs are classified according to their main electrophysiologic effects on cardiac cells (Table 4-1). Although this classification system has several shortcomings (e.g., some drugs having antiarrhythmic effects are excluded, several drugs have the multiclass effects, and focus on ion channel mechanisms is lacking), clinical reference to this classification persists. See Table 4-2 and Box 4-4 for antiarrhythmic drug dosages and CRI calculation methods.

Class I agents tend to slow conduction and decrease automaticity and excitability by means of their membrane-stabilizing effects; traditional ventricular antiarrhythmic drugs belong to this class. Class II drugs include the  $\beta$ -adrenergic antagonists ( $\beta$ -blockers), which act by inhibiting the effects of catecholamines on the heart. Class III drugs prolong the effective refractory period of cardiac action potentials without decreasing conduction velocity; they may be most effective in suppressing reentrant arrhythmias and in pre-

BOX 4-4

Formulas to Calculate Constant-Rate Infusion

#### Method 1

(Allows for "fine-tuning" fluid as well as drug administration

Determine desired drug infusion rate:  $\mu g/kg/min \times kg$ body weight =  $\mu g/min (A)$ 

Determine desired fluid infusion rate: ml/hour + 60 = ml/min (B)

(A) + (B) =  $\mu$ g/min + ml/min =  $\mu$ g drug/ml of fluid Convert from  $\mu$ g to mg of drug needed (1  $\mu$ g =

Mg drug/ml fluid  $\times$  ml of fluid in bag (or bottle, etc) = mg of drug to add to the fluid container

#### Method 2

(For total dose over a 6-hour period, must also calculate fluid volume and administration rate)

Total dose in mg to infuse over a 6-hour period = Body weight (kg)  $\times$  dose ( $\mu$ g/kg/min)  $\times$  0.36

#### Method 3 (for Lidocaine)

(Faster but less helpful if fluid rate is important or fine drugdosage adjustments are needed)

For CRI of 44  $\mu g/kg/min$  of lidocaine, add 25 ml of 2% lidocaine to 250 ml of  $D_5W$ 

Infuse at 0.25 ml/25 lb of body weight/min

venting VF. Class IV drugs are the calcium entry blockers; ventricular arrhythmias are usually not responsive to these agents, but they are important against supraventricular tachyarrhythmias. Antiarrhythmic agents within this classification scheme are contraindicated in animals with complete heart block and should be used only cautiously in animals with sinus bradycardia, sick sinus syndrome, and first- or second-degree AV block.

#### **CLASS I ANTIARRHYTHMIC DRUGS**

Class I antiarrhythmic drugs block membrane Na<sup>+</sup> channels and depress the action potential upstroke (phase 0), which slows conduction velocity along the cardiac cells. They have been subclassified according to differences in other electrophysiologic characteristics. These differences (see Table 4-1) may influence their efficacy against particular arrhythmias. Most of the Class I agents depend on extracellular K<sup>+</sup> concentration for their effects, and they lose effectiveness in patients with hypokalemia.

# Lidocaine

Lidocaine HCl is usually the first-choice IV ventricular antiarrhythmic agent in dogs. It is often ineffective against supraventricular arrhythmias. It has little effect on sinus node rate, AV conduction rate, and refractoriness. Lidocaine suppresses automaticity in normal Purkinje fibers and diseased myocardial tissue, slows conduction, and reduces the

TABLE 4-1

# Classification and Effects of Antiarrhythmic Drugs

CLASSIFICATION	DRUG	MECHANISM AND ECG EFFECTS
Class I		Decreases fast inward Na <sup>+</sup> current; membrane-stabilizing effects (decreased conductivity, excitability, and automaticity)
IA	Quinidine Procainamide Disopyramide	Moderately decreases conductivity, increases action potential duration; can prolong QRS complex and Q-T interval
IB	Lidocaine Mexiletine Phenytoin	Little change in conductivity, decreases action potential duration; QRS complex and Q-T interval unchanged
IC	Flecainide Encainide Propafenone	Markedly decreases conductivity without change in action potential duration
Class II	Propranolol Atenolol Esmolol Metoprolol Carvedilol Others	β-adrenergic blockade—reduces effects of sympathetic stimulation (no direct myocardial effects at clinical doses)
Class III	Sotalol Amiodarone Ibutilide Dofetilide Others	Selectively prolongs action potential duration and refractory period; antiadrenergic effects; Q-T interval prolonged
Class IV	Verapamil Diltiazem Others	Decreases slow inward Ca <sup>++</sup> current (greatest effects on sinoatrial and AV nodes)
Other Antiarrhythmic Agents	Digoxin  Atropine Glycopyrrolate	Antiarrhythmic action results mainly from indirect autonomic effects (especially increased vagal tone) Anticholinergic agents oppose vagal effects on SA and AV nodes (glycopyrrolate and other drugs also have this effect)
	Others Adenosine	Briefly opens K <sup>+</sup> channels and indirectly slows Ca <sup>++</sup> current (greatest effects on sinoatrial and AV nodes); may transiently block AV conduction, but ineffective in dogs

AV, atrioventricular; SA, sinoatrial.

supernormal period (during which the cell can be reexcited before complete repolarization occurs). It has greater effects on diseased and hypoxic cardiac cells and at faster stimulation rates. The electrophysiologic effects of lidocaine are dependent on the extracellular potassium concentration. Hypokalemia may render the drug ineffective, but hyperkalemia intensifies its depressant effects on cardiac membranes. Lidocaine produces little or no depression of contractility at therapeutic doses when administered slowly IV; this is useful in dogs with heart failure. The lidocaine congeners tocainide and mexiletine similarly produce minimal negative inotropic and hypotensive effects. Toxic concentrations of lidocaine can cause hypotension.

Lidocaine undergoes rapid hepatic metabolism; some metabolites may contribute to its antiarrhythmic and toxic effects. Lidocaine is not effective orally because of its almost complete first-pass hepatic elimination. IV administration, usually as slow boluses followed by CRI, is most effective. Antiarrhythmic effects after IV bolus occur within 2 minutes and abate within 10 to 20 minutes. CRI without a loading dose produces steady-state concentrations in 4 to 6 hours. The half-life is <1 hour in the dog. An initial bolus of 2 mg/kg is used in dogs and can be repeated two to three times if necessary. Lower doses should be used in cats to avoid toxicity (loading dose of 0.25 to 0.5 mg/kg). The half-life in cats is 1 to 2 hours. Therapeutic plasma concentrations are thought to range from 1.5 to 6  $\mu$ g/ml in dogs. Only lidocaine without epinephrine should be used for antiarrhythmic therapy. If IV access is not possible, IM administration could be used, but IV is much preferred.

The most common toxic effect of lidocaine is central nervous system excitation. Signs include agitation,

# TABLE 4-2 Dosage of Antiarrhythmic Drugs

AGENT	DOSAGE		
Class I			
Lidocaine	Dog: initial boluses of 2 mg/kg slowly IV, up to 8 mg/kg; or rapid IV infusion at 0.8 mg/kg/min; if effective, then 25-80 μg/kg/min CRI; can also be used intratracheally for CPR Cat: initial bolus of 0.25-0.5 (or 1.0) mg/kg slowly IV; can repeat boluses of 0.15-0.25 mg/kg, up to total of 4 mg/kg; if effective, 10-40 μg/kg/min CRI		
Procainamide	Dog: 6-10 (up to 20) mg/kg IV over 5-10 minutes; 10-50 µg/kg/min CRI; 6-20 (up to 30) mg/kg IM q4-6h; 10-25 mg/kg by mouth q6h (sustained release: q6-8h) Cat: 1.0-2.0 mg/kg slowly IV; 10-20 µg/kg/min CRI; 7.5-20 mg/kg IM or by mouth q(6-)8h		
Quinidine	Dog: 6-20 mg/kg IM q6h (loading dose, 14-20 mg/kg); 6-16 mg/kg by mouth q6h; sustained action preparations, 8-20 mg/kg by mouth q8h  Cat: 6-16 mg/kg IM or by mouth q8h		
Mexiletine	Dog: 4-10 mg/kg by mouth q8h Cat: —		
Phenytoin	Dog: 10 mg/kg slowly IV; 30-50 mg/kg by mouth q8h Cat: do not use		
Propafenone	Dog: (?) 3-4 mg/kg by mouth q8h Cat: —		
Flecainide	Dog: (?) 1-5 mg/kg by mouth q8-12h Cat: —		
Class II			
Atenolol	Dog: 0.2-1.0 mg/kg by mouth q12-24h Cat: 6.25-12.5 mg/cat by mouth q(12-)24h		
Propranolol	Dog: 0.02 mg/kg initial bolus slowly IV (up to maximum of 0.1 mg/kg); initial dose, 0.1-0.2 mg/kg by mouth q8h, up to 1 mg/kg q8h  Cat: Same IV instructions; 2.5 up to 10 mg/cat by mouth q8-12h		
Esmolol	Dog: 0.1-0.5 mg/kg IV over 1 minute (loading dose), followed by infusion of 0.025-0.2 mg/kg/min Cat: same		
Metoprolol	Dog: initial dose, 0.2 mg/kg by mouth q8h, up to 1 mg/kg q8(-12)h Cat: —		
Class III			
Sotalol	Dog: 1-3.5 (-5) mg/kg by mouth q12h Cat: 10-20 mg/cat by mouth q12h (or 2-4 mg/kg by mouth q12h)		
Amiodarone	Dog: 10 mg/kg by mouth q12h for 7 days, then 8 mg/kg by mouth q24h (lower as well as higher doses have been used); 3(-5) mg/kg slowly (over 10-20 min) IV (can repeat but do not exceed 10 mg/kg in 1 hour)  Cat: —		
Class IV			
Diltiazem	Dog: Oral maintenance: initial dose 0.5 mg/kg (up to 2+ mg/kg) by mouth q8h; acute IV for supraventricular tachycardia: 0.15-0.25 mg/kg over 2-3 min IV, can repeat every 15 minutes until conversion or maximum 0.75 mg/kg; CRI: 5-15 mg/kg/hr; oral loading dose: 0.5 mg/kg followed by 0.25 mg/kg by mouth q1h to a total of 1.5(-2.0) mg/kg or conversion Cat: Same?; for HCM: 1.5-2.5 mg/kg (or 7.5-10 mg/cat) by mouth q8h; sustained-release preparations: Cardizem-CD, 10 mg/kg/day (45 mg/cat is about 105 mg of Cardizem-CD, or the amount that fits into the small end of a No. 4 gelatin capsule); Diltiazem (Dilacor) XR, 30 mg/cat/day (one half of a 60-mg controlled-release tablet within the 240-mg gelatin capsule), can increase to 60 mg/day in some cats if necessary		
Verapamil	Dog: initial dose, 0.02-0.05 mg/kg slowly IV, can repeat q5min up to a total of 0.15(-0.2) mg/kg; 0.5-2 mg/kg by mouth q8h  Cat: initial dose, 0.025 mg/kg slowly IV, can repeat every 5 minutes up to a total of 0.15(-0.2) mg/kg; 0.5-1 mg/kg by mouth q8h		

# Dosage of Antiarrhythmic Drugs-cont'd

AGENT	DOSAGE	
Anticholinergic		
Atropine	Dog: 0.02-0.04 mg/kg IV, IM, SC; can also be given intratracheally for CPR; 0.04 mg/kg by mouth q6-8h Cat: same	
	Atropine challenge test: 0.04 mg/kg IV (see text, p. 93)	
Glycopyrrolate	Dog: 0.005-0.01 mg/kg IV or IM; 0.01-0.02 mg/kg SC	
, , ,	Cat: same	
Propantheline	Dog: 3.73-7.5 mg by mouth q8-12h Cat: —	
Hyoscyamine	Dog: 0.003-0.006 mg/kg by mouth q8h Cat: —	
Sympathomimetic		
Isoproterenol	Dog: 0.045-0.09 μg/kg/min CRI Cat: same	
Terbutaline	Dog: 2.5-5 mg/dog by mouth q8-12h Cat: 1.25 mg/cat by mouth q12h	
Other Agents		
Digoxin	See Table 3-3	
Adenosine	Dog: up to 12 mg as rapid IV bolus Cat: —	
Edrophonium	Dog: 0.05 to 0.1 mg/kg IV (have atropine and endotracheal tube available) Cat: same?	
Phenylephrine	Dog: 0.004 to 0.01 mg/kg IV Cat: same?	

CRI, Constant rate infusion; CPR, cardiopulmonary resuscitation; -, effective dosage not known.

disorientation, muscle twitches, nystagmus, and generalized seizures. The latter may require diazepam (0.25 to 0.5 mg/kg IV) or a short-acting barbiturate. Nausea can also occur. Worsening of arrhythmias (a proarrhythmic effect) is seen occasionally, as it is with any drug having cardiac electrophysiologic effects. Cats are particularly sensitive to the drug's toxic effects and may undergo respiratory arrest along with seizures. In the event of toxicity, lidocaine should be discontinued until the signs of toxicity disappear; a lower infusion rate may then be instituted. IV diazepam (0.25 to 0.5 mg/kg) is used to control lidocaine-induced seizures. There are anecdotal reports of respiratory depression and arrest after the administration of lidocaine in unconscious dogs and cats. Propranolol, cimetidine, and other drugs that decrease liver blood flow slow the metabolism of lidocaine and predispose to the development of toxicity. Animals with heart failure may also have reduced hepatic blood flow and may require a lower dosage of the drug. Hepatic disease can delay elimination as well.

### **Procainamide**

Procainamide HCl has electrophysiologic effects similar to those of quinidine. Procainamide has both direct and indirect (vagolytic) effects; it is indicated for the treatment of premature ventricular (and sometimes atrial) depolarizations and tachycardias. It is less effective than quinidine in managing atrial arrhythmias and is usually not effective in converting chronic atrial flutter-fibrillation to sinus rhythm. Procainamide should be used only with caution in animals with hypotension.

Orally administered procainamide is well absorbed in the dog but has a half-life of only 2.5 to 4 hours. The sustained-release preparation has a slightly longer half-life of 3 to 6 hours. Food may delay the absorption of procainamide. The drug undergoes hepatic metabolism and renal excretion in proportion to the creatinine clearance. The metabolite N-acetylprocainamide is not clinically important in dogs and cats. Procainamide can be given orally or intramuscularly without marked hemodynamic effects, but rapid IV injection can cause hypotension and cardiac depression, although to a much lesser degree than IV quinidine. Administration by CRI can be useful if the arrhythmia responds to an IV bolus; a steady state is reached in 12 to 22 hours. Therapeutic plasma concentrations are thought to be 4 to 10 µg/ml.

The toxic effects of procainamide are similar to those of quinidine (discussed in the following section) but are usually milder. Gastrointestinal upset and prolongation of the QRS or QT intervals may occur. Procainamide can enhance the ventricular response rate to AF if used without digoxin or a β- or Ca<sup>++</sup> blocker. More serious toxic effects include hypotension, depressed AV conduction (sometimes causing second- or third-degree heart block), and proarrhythmia. The latter can cause syncope or VF. Hypotension responds to IV fluids, catecholamines, or calcium-containing solutions. Gastrointestinal signs associated with oral therapy may respond to dosage reduction. High-dose oral procainamide therapy in people has been associated with a reversible lupus-like syndrome characterized by neutropenia, fever, depression, and hepatomegaly, but this has not been documented in dogs. Long-term use can cause brown discoloration of the haircoat in black Doberman Pinschers.

#### Quinidine

Quinidine has been used to treat ventricular and, occasionally, supraventricular tachyarrhythmias. In large dogs with recent-onset AF and normal ventricular function, quinidine may cause conversion to sinus rhythm. This drug must be used cautiously in animals with heart failure or hyperkalemia. The characteristic electrophysiologic effects of quinidine are depression of automaticity and conduction velocity and prolongation of the effective refractory period. Corresponding dose-dependent ECG changes (e.g., PR, QRS, and QT prolongation) result from direct electrophysiologic and vagolytic effects. At low doses, quinidine's vagolytic effects may increase the sinus rate or the ventricular response rate to AF by antagonizing the drug's direct effects. As with other class I agents, hypokalemia reduces quinidine's antiarrhythmic effectiveness.

The drug is well-absorbed orally but has fallen out of favor for chronic oral therapy because of its frequent adverse effects and its interference with digoxin pharmacokinetics. Quinidine is metabolized extensively by the liver, with little dependence on liver blood flow. The half-life is about 6 hours in dogs and 2 hours in cats. Quinidine is highly protein-bound; severe hypoalbuminemia can predispose to toxicity. Cimetidine can also predispose to toxicity by slowing the drug's elimination. Quinidine can precipitate digoxin toxicity (when used concurrently) by displacing digoxin from skeletal muscle binding sites and reducing its renal clearance. Anticonvulsants and other drugs that induce hepatic microsomal enzymes can speed quinidine's metabolism. IV administration is not recommended because of quinidine's propensity to cause vasodilation (by means of nonspecific α-adrenergic receptor blockade), cardiac depression, and hypotension. The oral and IM routes usually do not cause adverse hemodynamic effects, but close monitoring is warranted initially, especially in animals with underlying cardiac disease. Therapeutic blood concentrations are thought to be 2.5 to  $5 \mu g/ml$  and are usually achieved in 12 to 24 hours after oral and IM administration. Slow-release sulfate (83% active drug), gluconate (62% active drug), and polygalacturonate (80% active drug) salts of quinidine prolong the drug's absorption and elimination. The sulfate salt is more rapidly absorbed than the gluconate; peak effect is usually achieved 1 to 2 hours after oral administration.

Quinidine toxicity occurs as an extension of the drug's electrophysiologic and hemodynamic actions. As the plasma concentration increases, the PR interval and QRS duration lengthen. Marked QT prolongation, right bundle-branch block, or QRS widening >25% of pretreatment value suggests drug toxicity; various conduction blocks and ventricular tachyarrhythmias are other manifestations. Marked QT prolongation implies increased temporal dispersion of myocardial refractoriness; this predisposes to torsades de pointes (see p. 25) and VF. Transient episodes of these serious arrhythmias can be a cause of syncopal attacks in people taking quinidine. Lethargy, weakness, and CHF can result from the negative inotropic and vasodilatory effects of the drug and subsequent hypotension. Cardiotoxicity and hypotension can be partially reversed by sodium bicarbonate (1 mEq/kg IV), which temporarily decreases serum K<sup>+</sup> concentration, enhances quinidine's binding to albumin, and reduces its cardiac electrophysiologic effects. Gastrointestinal signs (e.g., nausea, vomiting, diarrhea) are common with orally administered quinidine. Thrombocytopenia (reversible after quinidine discontinuation) can occur in people and possibly in dogs and cats.

#### Mexiletine

Mexiletine HCl is similar to lidocaine in its electrophysiologic, hemodynamic, toxic, and antiarrhythmic properties. It can be effective in suppressing ventricular tachyarrhythmias in dogs. The combination of a β-blocker (or procainamide or quinidine) with mexiletine may be more efficacious and associated with fewer adverse effects than mexiletine alone. The drug is easily absorbed when administered orally, but antacids, cimetidine, and narcotics reportedly slow its absorption in people. Mexiletine undergoes hepatic metabolism (influenced by liver blood flow) and some renal excretion (which is slower if the urine is alkaline). Hepatic microsomal enzyme inducers may accelerate its clearance. The half-life in dogs is from 4.5 to 7 hours (depending to some degree on the urine pH). Approximately 70% of the drug is protein bound. The therapeutic serum concentration is thought to range from 0.5 to 2.0  $\mu$ g/ml (as in people). The effects of this drug in cats are not known. Adverse effects have included vomiting, anorexia, tremor, disorientation, sinus bradycardia, and thrombocytopenia. Overall, mexiletine appears to produce fewer adverse effects than tocainide.

### Phenytoin

Phenytoin's electrophysiologic effects are similar to those of lidocaine. It also has some slow-calcium channel inhibitory and central nervous system effects that may contribute to its effectiveness against digitalis-induced arrhythmias. This drug is currently used only for digitalis-induced ventricular arrhythmias that have not responded to lidocaine in dogs. Its contraindications are the same as for lidocaine. Slow IV infusion and oral administration do not cause relevant hemodynamic disturbances; however, the oral bioavailability of phenytoin is poor. Rapid IV injection should be avoided

because the propylene glycol vehicle can depress myocardial contractility, exacerbate arrhythmias, and cause vasodilation, hypotension, or respiratory arrest. The half-life of phenytoin in the dog is about 3 hours. The drug is metabolized in the liver, and it may speed up its own elimination by stimulating hepatic microsomal enzymes. Co-administration of cimetidine, chloramphenicol, and other drugs that inhibit microsomal enzyme activity increases phenytoin's serum concentration. The IV administration of phenytoin has been associated with bradycardia, AV blocks, ventricular tachycardia, and cardiac arrest. Other manifestations of phenytoin toxicity include central nervous system signs (e.g., depression, nystagmus, disorientation, ataxia). The drug is not used in cats because its half-life is >40 hours, and even low doses produce toxic serum concentrations in this species.

# Other Class I Agents

Disopyramide is similar to quinidine and procainamide electrophysiologically. It has a very short half-life in the dog (<2 hours), as well as marked depressive effects on the canine myocardium. Tocainide, a class IB agent similar to lidocaine, is no longer available in the United States. Flecainide and propafenone are class IC agents. They produce marked reduction in cardiac conduction velocity but have little effect on sinus rate or refractoriness. High doses depress automaticity in the sinus node and specialized conducting tissues. Vasodilation and myocardial depression can result in severe hypotension after IV injection, especially in animals with underlying cardiac disease. Proarrhythmia is a serious potential adverse effect of these agents. Bradycardia, intraventricular conduction disturbance, and consistent (although transient) hypotension, as well as nausea, vomiting, and anorexia, have occurred in dogs. Flecainide (and encainide) have been associated with increased mortality in people. These agents are rarely (and cautiously) used for treating life-threatening ventricular arrhythmias refractory to other therapy.

# CLASS II ANTIARRHYTHMIC DRUGS: β-ADRENERGIC BLOCKERS

Class II antiarrhythmic drugs act by blocking catecholamine effects. They slow heart rate, reduce myocardial O2 demand, and increase AV conduction time and refractoriness. The antiarrhythmic effect of β-blockers relates to β<sub>1</sub>-receptor blockade rather than direct electrophysiologic effects. They are often used in combination with a class I agent (e.g., procainamide or mexiletine), although their negative inotropic effect demands caution when used in animals with myocardial failure. B-receptor blockers are used in animals with hypertrophic cardiomyopathy, certain congenital and acquired ventricular outflow obstructions, systemic hypertension, hyperthyroid heart disease, supraventricular and ventricular tachyarrhythmias (especially those induced by enhanced sympathetic tone), and other diseases or toxicities that cause excessive sympathetic stimulation. A \(\beta\)-blocker is often used in conjunction with digoxin to slow the ventricular response rate to AF. A β-blocker such as propranolol or atenolol is considered the first-line antiarrhythmic agent in cats for the treatment of both supraventricular and ventricular tachyarrhythmias. In people with stable heart failure, long-term therapy with certain \( \beta \)-blockers improves cardiac function and prolongs survival in those who tolerate the drug (see p. 69).

β-adrenergic receptors have been classified into subtypes.  $\beta_1$ -receptors are located primarily in the myocardium and mediate increases in contractility, heart rate, AV conduction velocity, and automaticity in specialized fibers. Extracardiac  $\beta_2$ -receptors mediate bronchodilation and vasodilation, as well as renin and insulin release. There are also some  $\beta_2$ - as well as  $\beta_3$ -receptors in the heart. "Nonselective"  $\beta$ -blockers inhibit catecholamine binding to both  $\beta_1$ - and  $\beta_2$ -adrenergic receptors. Other  $\beta$ -blockers are more selective; they antagonize mainly one or the other receptor subtype (Table 4-3). The first-generation  $\beta$ -blockers (e.g., propranolol) have nonselective  $\beta$ -blocking effects. Second-generation agents

Characteristics of Selected \( \beta \)-Blockers

DRUG	ADRENERGIC RECEPTOR SELECTIVITY	LIPID SOLUBILITY	MAIN ROUTE OF ELIMINATION
Atenolol	$eta_1$	0	RE
Carvedilol	$\beta_1, \beta_2, \alpha_1$	+	HM
Esmolol	$\beta_1$	О	BE
Labetalol	$\beta_1, \beta_2, \alpha_1$	++	HM
Metoprolol	$\beta_1$	++	HM
Nadolol	$\beta_1$ , $\beta_2$	0	RE
Pindolol*	$\beta_1$ , $\beta_2$	++	В
Propranolol	$\beta_1$ , $\beta_2$	++	HM
Sotalol**	$\beta_1, \beta_2$	0	RE
Timolol	$\beta_1, \beta_2$	0	RE

<sup>\*</sup> Has intrinsic sympathomimetic activity.

<sup>\*\*</sup> Also has class III antiarrhythmic activity.

RE, Renal excretion; BE, blood esterases; HM, hepatic metabolism; B, both renal excretion and hepatic metabolism are important.

(e.g., atenolol, metoprolol) are relatively  $\beta_1$  selective. The third-generation  $\beta$ -blockers affect both  $\beta_1$  and  $\beta_2$  receptors but also antagonize  $\alpha_1$  receptors and may have other effects. A few  $\beta$ -blockers have some degree of intrinsic sympathomimetic activity.

The clinical antiarrhythmic effect of class II drugs is thought to relate to  $\beta_1$ -receptor blockade rather than to direct electrophysiologic mechanisms. In normal animals β-receptor blockers have little negative inotropic effect. However, they must be used cautiously in animals with underlying myocardial disease because increased sympathetic drive may be needed to maintain cardiac output. Marked depression of cardiac contractility, conduction, or heart rate can result in such cases. β-blockers are generally contraindicated in patients with sinus bradycardia, sick sinus syndrome, high-grade AV block, or severe CHF and in animals also receiving a Ca+1-blocking drug. Nonselective β-blockers may increase peripheral vascular resistance (because of unopposed  $\alpha$ -adrenergic effects) and provoke bronchoconstriction. β-blockers may also mask the early signs of acute hypoglycemia in diabetics (e.g., tachycardia and blood pressure changes), and reduce the release of insulin in response to hyperglycemia. Because the effect of β-blockers depends on the level of sympathetic activation, individual patient response is quite variable. Therefore initial dosages should be low and cautiously titrated upward as needed.

β-blockers enhance the depression of AV conduction produced by digitalis, class I antiarrhythmic drugs, and Ca<sup>++</sup>-blockers. Use of a β-blocker and a Ca<sup>++</sup>-blocker simultaneously can markedly decrease heart rate and myocardial contractility. Because of possible β-receptor upregulation (increased number or affinity of receptors) during long-term  $\beta$ -blockade, therapy should not be abruptly discontinued.

#### **Propranolol**

Propranolol HCl is a nonselective  $\beta$ -blocker that was widely used in dogs and cats, although atenolol is used more often now. Propranolol is not recommended for patients with pulmonary edema because of the potential for bronchoconstriction caused by  $\beta_2$ -receptor antagonism. The  $\beta_2$ -receptor blocking effects of propranolol also make it relatively contraindicated in patients with asthma or chronic small airway disease.

Propranolol undergoes extensive first-pass hepatic metabolism, so oral bioavailability is low; but with time and use of higher doses hepatic enzymes become saturated and bioavailability increases. Propranolol reduces hepatic blood flow, which prolongs its elimination as well as that of other drugs dependent on liver blood flow for their metabolism (e.g., lidocaine). Feeding delays oral absorption and increases drug clearance after IV dosing (by increasing hepatic blood flow). The half-life of propranolol in the dog is only about 1.5 hours (0.5 to 4.2 hours in cats). Active metabolites exist and dosing every 8 hours appears to be adequate in both species. IV propranolol is used mainly for refractory ventricular tachycardia (in conjunction with a class I

drug) and for emergency treatment of atrial or junctional tachycardia.

Toxicity is most often related to excessive  $\beta$ -blockade; this can develop at relatively low doses in some animals. Bradycardia, heart failure, hypotension, bronchospasm, and hypoglycemia can occur. Infusion of a catecholamine (e.g., dopamine or dobutamine) will help reverse these effects. Propranolol and other lipophilic  $\beta$ -blockers can cause central nervous system effects such as depressed attitude and disorientation.

#### **Atenolol**

Atenolol is a selective  $\beta_1$ -blocker. It is used commonly to slow sinus rate and AV conduction and to suppress ventricular premature beats. The half-life of atenolol is slightly more than 3 hours in dogs and about 3.5 hours in cats. Its oral bioavailability in both species is high (~90%). Atenolol is excreted in the urine, so renal dysfunction delays its clearance. Atenolol's  $\beta$ -blocking effect lasts more than 12 hours but less than 24 hours in normal cats. This drug is hydrophilic. Adverse central nervous system effects are unlikely because it does not readily cross the blood-brain barrier. As with other  $\beta$ -blockers, weakness or exacerbation of heart failure can occur.

# Metoprolol

Metoprolol tartrate is another  $\beta_1$ -selective agent. It is well absorbed orally, but bioavailability is reduced by a large first-pass effect. There is minimal protein-binding. The drug is metabolized in the liver and excreted in the urine. Half-life is 1.6 hours in dogs and 1.3 hours in cats. Metoprolol has been used in some dogs with dilated cardiomyopathy and chronic valvular disease. It may possibly contribute to improved cardiac function over time (see p. 69).

#### Esmolol

Esmolol HCl is an ultra-short acting  $\beta_1$ -selective agent. It is rapidly metabolized by blood esterases and has a half-life of <10 minutes. Steady state occurs in 5 minutes after a loading dose or 30 minutes without. Esmolol's effects are gone within 10 to 20 minutes after infusion is terminated. This drug is used for acute therapy of tachyarrhythmias and feline hypertrophic obstructive cardiomyopathy.

# Other **B-Blockers**

Many other  $\beta$ -blocking drugs are available. Their receptor selectivity as well as their pharmacologic characteristic vary. Certain  $\beta$ -blockers may prove useful in patients with chronic, stable myocardial failure by reducing the cardiotoxic effects of excessive sympathetic stimulation, improving cardiac function, promoting upregulation of cardiac  $\beta$ -receptors, and increasing survival time (see p. 69). The third-generation  $\beta$ -blocker, carvedilol, and the second-generation agent, metoprolol, are effective in this regard. Nonselective (first-generation) agents, such as propranolol, and some later-generation agents do not appear to confer these survival benefits.

Agents with intrinsic sympathomimetic activity appear to have deleterious effects.

# CLASS III ANTIARRHYTHMIC DRUGS

Common features of class III drugs include prolongation of the cardiac action potential and effective refractory period without a decrease in conduction velocity. Their effects are mediated by inhibition of potassium channels responsible for repolarization (delayed rectifier current). These agents are useful for ventricular arrhythmias, especially those caused by reentry. Class III drugs have antifibrillatory effects as well. They share some characteristics of other antiarrhythmic drug classes in addition to their class III effects.

#### Sotalol

Sotalol HCl is a nonselective  $\beta$ -blocker that has Class III effects at higher doses. Its oral bioavailability is high, although absorption is reduced when given with food. Sotalol's halflife is about 5 hours in dogs. It is eliminated unchanged by the kidneys, and renal dysfunction prolongs elimination. Sotalol's \( \beta\)-blocking effect outlasts its plasma half-life. The drug has minimal hemodynamic effects, although it can cause slowed sinus rate, first-degree AV block, and hypotension. Proarrhythmia can occur (as with all antiarrhythmic agents), including torsades de pointes. Sotalol's class III effects occur at higher doses in dogs than in people. Doses used clinically in dogs may be producing primarily β-blocking effects. On the other hand, a high incidence of proarrhythmia (especially torsades de pointes), of concern in people taking sotalol, has not been reported clinically in dogs. Experimentally, in dogs with hypokalemia, coadministration of mexiletine reduced the proarrhythmic potential.

Sotalol may worsen heart failure in animals with dilated cardiomyopathy. However, sotalol is thought to have less negative inotropic effect than propranolol. Other adverse effects of sotalol have included hypotension, depression, nausea, vomiting, diarrhea, and bradycardia. There are occasional anecdotal reports of aggression that resolved after sotalol was discontinued.

### **Amiodarone**

Amiodarone HCl is thought to produce its antiarrhythmic effects by prolonging the action potential duration and effective refractory period in both atrial and ventricular tissues. Although considered a class III agent, it shares properties with all three other antiarrhythmic drug classes. Amiodarone is an iodinated compound that also has noncompetitive  $\alpha_{t^-}$  and  $\beta$ -blocking effects, as well as  $Ca^{++}$  channel-blocking effects. The  $\beta$ -blocking effects occur soon after administration, but maximal class III effects (and prolongation of action potential duration and QT interval) are not achieved for weeks with chronic administration. Its  $Ca^{++}$  blocking effects may inhibit triggered arrhythmias by reducing afterdepolarizations. Therapeutic doses slow the sinus rate, decrease AV conduction velocity, and minimally depress myocardial contractility and blood pressure. Indications for

amiodarone include refractory atrial and ventricular tachyarrhythmias, especially reentrant arrhythmias using an accessory pathway. The IV form is used in people with AF, ventricular tachycardia, and during cardiopulmonary resuscitation from recurrent ventricular tachycardia and fibrillation; similar applications are expected in dogs. However, conservative dosing with slow injection over 10 to 20 minutes is recommended, because IV use can cause hypotension and bradycardia. The drug is also given by CRI in people; 10 to 15 mg/kg/day has been used in children.

The pharmacokinetics of amiodarone are complex. Chronic oral use is associated with a prolonged time to steady state (of several weeks), concentration of drug in myocardial and other tissues, and accumulation of an active metabolite (desethylamiodarone). Therapeutic serum concentration is thought to be 1 to 2.5  $\mu$ g/ml. Amiodarone may have less of a proarrhythmic effect than other agents and may reduce the risk of sudden death because of uniform prolongation of repolarization throughout the ventricles, as well as suppression of Purkinje fiber automaticity. In normal dogs IV amiodarone does not adversely affect contractility at cumulative doses less than 12.5 to 15 mg/kg. However, the potential exists for more profound cardiac depression and hypotension in dogs with myocardial disease. Amiodarone use is not described in cats.

Long-term amiodarone is associated with many potential adverse effects, including depressed appetite, gastrointestinal upset, pneumonitis leading to pulmonary fibrosis, hepatopathy, thyroid dysfunction, positive Coombs test, thrombocytopenia, and neutropenia. Occasional hypersensitivity reactions (with acute angioedema formation) or of tremors have occurred in dogs. Other adverse effects observed in people have included corneal microdeposits, photosensitivity, bluish skin discoloration, and peripheral neuropathy. Amiodarone can increase the serum concentration of digoxin, diltiazem, and possibly procainamide and quinidine.

# Other Class III Agents

Ibutilide fumarate is somewhat effective for converting recent-onset AF in people, but there is little veterinary experience with this drug. In experimental rapid-pacing—induced cardiomyopathy in dogs, ibutilide caused episodes of torsades de pointes.

Dofetilide is another drug that selectively blocks the rapid component of the K' current responsible for repolarization. It too is used in people for the conversion of AF and to maintain sinus rhythm. Its efficacy for this appears to be comparable to that of other class III drugs, and it does not exacerbate left ventricular dysfunction. Bretylium tosylate is no longer available in the United States.

# CLASS IV ANTIARRHYTHMIC DRUGS: CALCIUM ENTRY BLOCKERS

The Ca<sup>++</sup> entry blockers are a diverse group of drugs that have the common property of decreasing cellular Ca<sup>++</sup> influx by blocking transmembrane L-type calcium channels. As a

group, these drugs can cause coronary and systemic vasodilation, enhance myocardial relaxation, and reduce cardiac contractility. Some calcium entry blockers have antiarrhythmic effects, especially on tissues dependent on the slow inward Ca<sup>++</sup> current, such as the sinus and AV nodes. Other conditions for which calcium entry blockers are potentially useful include hypertrophic cardiomyopathy, myocardial ischemia, and hypertension.

Possible adverse effects of these agents include reduced contractility, vasodilation, hypotension, depression, anorexia, lethargy, bradycardia, and AV block. Low initial doses are used and increased as needed to effect or to maximal recommended dose. Contraindications to  $Ca^{++}$  channel blocker use include sinus bradycardia, AV block, sick sinus syndrome, digoxin toxicity, and myocardial failure (for agents with pronounced negative inotropic effect). They are usually not prescribed in patients receiving a  $\beta$ -blocker because of additive negative effects on contractility, AV conduction, and heart rate. An overdose or exaggerated response to a  $Ca^{++}$  blocker is treated with supportive care, including atropine for bradycardia or AV block, dopamine or dobutamine (see Box 3-1) and furosemide for heart failure, and dopamine or IV calcium salts for hypotension.

# **Diltiazem**

Diltiazem HCl is a benzothiazepine Ca<sup>-+</sup> channel blocker. It slows AV conduction, causes potent coronary and mild peripheral vasodilation, and has a lesser negative inotropic effect than the prototypical calcium entry blocker, verapamil. Diltiazem is often combined with digoxin to further slow the ventricular response rate to AF in dogs. It is indicated for other supraventricular tachyarrhythmias as well. Diltiazem is often used in cats with hypertrophic cardiomyopathy; its beneficial effects can include enhanced myocardial relaxation and perfusion, as well as a mild decrease in heart rate, contractility, and myocardial oxygen demand (see Chapter 8). Chronic diltiazem therapy may be associated with a decrease in left ventricular wall and septal thickness in cats with hypertrophic cardiomyopathy.

Peak effects are seen within 2 hours of oral dosing, and the effects last at least 6 hours in dogs. Extensive first-pass effect limits bioavailability, especially in dogs. The half-life of diltiazem in the dog is just over 2 hours, but chronic oral treatment prolongs it because of enterohepatic circulation. In cats plasma diltiazem concentration peaks in 30 minutes, and the effects last for 8 hours. The therapeutic range is 50 to 300 ng/ml. Diltiazem is metabolized in the liver; active metabolites exist. Drugs that inhibit hepatic enzyme systems (e.g., cimetidine) decrease the metabolism of diltiazem. Propranolol and diltiazem reduce each other's clearance when used simultaneously. A sustained-release preparation (Cardizem-CD), at 10 mg/kg daily in cats, produces plasma concentrations that peak in 6 hours and remain in the therapeutic range for 24 hours. A dose of 45 mg per cat is approximately equal to 105 mg of Cardizem-CD (or the amount that fits into the small end of a No. 4 gelatin capsule; a 300-mg capsule provides about 6.5 doses); this is given once daily. Diltiazem XR is another sustainedrelease diltiazem preparation. The 240-mg capsule contains four 60-mg tablets. There is much intercat variability in pharmacokinetics with this form. Higher doses are more likely to be associated with anorexia and other gastrointestinal signs.

Adverse effects of diltiazem are uncommon at therapeutic doses, although anorexia, nausea, and bradycardia may occur. Rarely, other gastrointestinal, cardiac, and neurologic adverse effects develop. High liver enzyme activities and anorexia occur sporadically in cats. Some cats have become aggressive or shown other personality change when treated with diltiazem.

# Verapamil

Verapamil HCl is a phenylalkylamine and has the most potent cardiac effects of the Ca<sup>++</sup>-blockers used clinically. The drug increases the refractory period of nodal tissues and can abolish reentrant SVT as well as slow the ventricular response rate in AF. Verapamil causes dose-related slowing of the sinus rate and AV conduction. It is sometimes used for supraventricular and atrial tachycardias in animals without heart failure. Verapamil's half-life in dogs is about 2.5 hours. It is poorly absorbed and undergoes first-pass hepatic metabolism, resulting in low bioavailability with oral use. The pharmacokinetics in cats are similar to those of dogs.

The drug has important negative inotropic and some vasodilatory effects that can cause cardiac decompensation, hypotension, and even death in the presence of underlying myocardial disease. An initially low IV dose is given very slowly; this can be repeated at 5- (or more) minute intervals if no adverse effects have occurred and the arrhythmia persists. Blood pressure monitoring is advisable because of the potential for hypotension. As discussed above, verapamil is not recommended for use in animals with heart failure. The toxic effects of verapamil include sinus bradycardia, AV block, hypotension, reduced myocardial contractility, and cardiogenic shock. Verapamil reduces the renal clearance of digoxin.

# Other Calcium Channel Blockers

A number of other Ca<sup>++</sup>-blockers are available. Most (dihydropyridine group) are used as antihypertensives. Amlodipine besylate is recommended as the first-line antihypertensive agent in cats and is also used in some hypertensive dogs (see Chapter 11). Amlodipine is also used in the treatment of chronic refractory heart failure in some dogs (see Table 3-3). The drug is not useful as an antiarrhythmic agent. Nifedipine is another potent vasodilator without antiarrhythmic effects.

# ANTICHOLINERGIC DRUGS Atropine and Glycopyrrolate

Anticholinergic drugs increase sinus node rate and AV conduction when vagal tone is increased (see Table 4-2). Parenteral atropine or glycopyrrolate is indicated for bradycardia

or AV block induced by anesthesia, central nervous system lesions, and certain other diseases or toxicities. Atropine is a competitive muscarinic receptor antagonist that is used to determine whether excess vagal tone is responsible for arrhythmias attributed to sinus and/or AV nodal dysfunction. This is known as the atropine challenge test (or atropine response test). Response to atropine challenge is most consistent with IV administration of 0.04 mg/kg. An ECG is recorded within 5 to 10 minutes after atropine injection. If the heart rate has not increased by at least 150%, the ECG is repeated 15 (to 20) minutes after atropine injection; sometimes, an initial vagomimetic effect on the AV node lasts longer than 5 minutes. The normal sinus node response is a rate increase to 150 to 160 beats/minute (or >135 beats/ minute). A positive response may not predict response to oral anticholinergic therapy. Atropine has little to no effect on bradyarrhythmias caused by intrinsic disease of the sinus or AV node.

Atropine given by any parenteral route can transiently exacerbate vagally mediated AV block when the atrial rate increases faster than AV conduction can respond. However, IV administration causes the fastest and most consistent onset and resolution of the exacerbated block, as well as the most rapid postbradycardia heart rates, compared with the IM and subcutaneous routes. Unlike atropine, glycopyrrolate does not have centrally mediated effects, and its effects are longer-lasting than those of atropine.

# Oral Anticholinergic Drugs

Some animals that respond to parenteral atropine or glycopyrrolate will also respond to an oral anticholinergic agent. Clinical signs may be relieved in these animals, at least for a time. Nevertheless, animals with symptomatic bradyarrhythmias usually require permanent pacemaker implantation to effectively control heart rate. Propantheline bromide and hyoscyamine sulfate are commonly used, but other oral anticholinergic agents are also available. Individual dosage is adjusted to effect. Oral absorption of propantheline is variable; food may decrease drug absorption.

Vagolytic drugs can aggravate paroxysmal supraventricular tachyarrhythmias (as in sick sinus syndrome) and should be used only cautiously as chronic therapy in those patients. Other adverse effects of anticholinergic therapy include vomiting, dry mouth, constipation, keratoconjunctivitis sicca, increased intraocular pressure, and drying of respiratory secretions.

#### SYMPATHOMIMETIC DRUGS

Isoproterenol HCl is a  $\beta$ -receptor agonist that has been used to treat symptomatic AV block or bradycardia refractory to atropine, although electrical pacing is safer and more effective. It also can be effective for torsades de pointes. Because of its affinity for  $\beta_2$ -receptors, isoproterenol can cause hypotension. It is not used for treating either heart failure or cardiac arrest. Isoproterenol can be arrhythmogenic, as can other catecholamines. The lowest effective dose (see Table 4-2) is used, and the animal is monitored closely for arrhyth-

mias. Oral administration is not effective because of marked first-pass hepatic metabolism.

Terbutaline sulfate is a  $\beta_2$ -receptor agonist that may have a mild stimulatory effect on heart rate when given orally. Methylxanthine bronchodilators (e.g., aminophylline and theophylline) increase heart rate in some dogs with sick sinus syndrome when used at higher doses.

#### OTHER DRUGS

Edrophonium chloride is a short-acting anticholinesterase with nicotinic and muscarinic effects. Although mainly used for diagnosing myasthenia gravis, it slows AV conduction, which can help in the diagnosis and resolution of some cases of acute SVT. The drug's effect begins within 1 minute and lasts up to 10 minutes after IV injection. Adverse effects are primarily cholinergic and include gastrointestinal (e.g., vomiting, diarrhea, salivation), respiratory (e.g., bronchospasm, respiratory paralysis, edema), cardiovascular (e.g., bradycardia, hypotension, cardiac arrest), and muscular (e.g., twitching, weakness) signs. Atropine and supportive care are used if necessary.

Phenylephrine HCl is an α-adrenergic agonist that increases blood pressure by peripheral vasoconstriction. A baroreflex-mediated increase in vagal tone slows AV conduction and is thought to underlie its effects on SVT. Phenylephrine's pressor effect begins rapidly after IV injection and persists for up to 20 minutes. The drug is contraindicated in patients with hypertension or ventricular tachycardia. Extravasation can cause ischemic necrosis of surrounding tissue

Other Vascular Anomalies

#### **GENERAL CONSIDERATIONS**

Common congenital cardiac malformations, as well as some that occur more sporadically, are described in this chapter. Most congenital heart defects produce an audible murmur (Fig. 5-1), although some serious malformations do not. Murmurs caused by congenital disease range in intensity from very loud to very soft depending on the type and severity of the defect and on hemodynamic factors. In addition to murmurs of congenital disease, clinically insignificant "innocent" murmurs are relatively common in puppies and kittens. Innocent murmurs are usually soft systolic ejection—type murmurs heard best at the left heart base; their intensity may vary with heart rate or body position. Innocent murmurs tend to get softer and usually disappear by about 4 months

of age. Murmurs caused by congenital disease usually persist and may get louder with time, although this is not always the case. Careful examination and auscultation are important, not only in animals intended for breeding but also in working dogs and pets. Puppies and kittens with a soft murmur and no other clinical or radiographic signs can be ausculted repeatedly as they grow to determine if the murmur disappears. Further diagnostic tests are indicated in animals with a persistent or loud murmur, those that manifest other signs, and those for which economic or breeding-potential decisions are pending. Adult dogs and cats with a previously undiagnosed congenital defect may or may not manifest clinical signs of disease at presentation.

Congenital heart defects most often involve either a valve (or valve region) or an abnormal communication between the systemic and pulmonary circulations. Abnormally formed valves can be insufficient, stenotic, or both. Other malformations can exist, and multiple anomalies occur in some patients. Congenital malformations vary widely in type and severity. The patient's prognosis and options for therapy depend on the definitive diagnosis as well as severity. Initial noninvasive testing usually includes thoracic radiographs, an electrocardiogram (ECG), and echocardiographic studies (M-mode, 2-dimensional [2-D], and Doppler). A packed cell volume (PCV) documents erythrocytosis in some cases with right-to-left shunting. Cardiac catheterization with selective angiocardiography can be useful to define some structural abnormalities or severity and is needed during transvascular interventional procedures. Surgical repair or palliation, balloon valvuloplasty, transcatheter shunt occlusion, or other interventional techniques may be helpful for some cases.

Patent ductus arteriosus (PDA) and subaortic stenosis (SAS) have been identified in different surveys as the most common congenital cardiovascular anomaly in the dog; pulmonic stenosis (PS) is also quite common. Persistent right aortic arch (a vascular ring anomaly), ventricular septal defect (VSD), malformations (dysplasia) of the atrioventricular (AV) valves, atrial septal defect (ASD), and tetralogy of Fallot (T of F) occur less frequently but are not rare. An AV septal (endocardial cushion) defect consists of all or

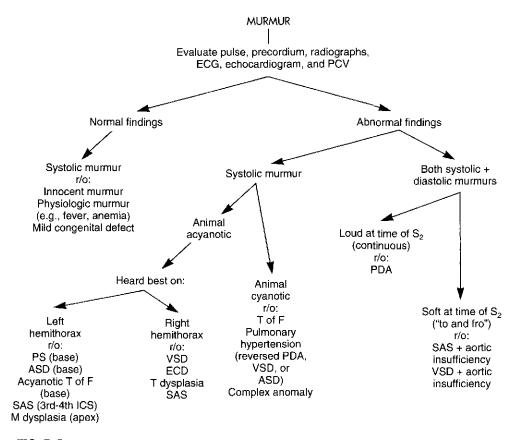

FIG 5-1

Flow chart for differentiating murmurs in puppies and kittens. ASD, Atrial septal defect; ECD, endocardial cushion defect; ECG, electrocardiogram; ICS, intercostal space; M, mitral valve; PCV, packed cell volume; PDA, patent ductus arteriosus; r/o, rule out; SAS, subaortic stenosis; T, tricuspid valve; T of F, tetralogy of Fallot; VSD, ventricular septal defect.

some of the following: a high VSD, a low ASD, and malformations of one or both AV valves. The most common malformations in cats are AV valve dysplasias and atrial or ventricular septal defects; other lesions include SAS, PDA, T of F, and PS. Endocardial fibroelastosis, mainly in Burmese and Siamese cats, also has been reported. Congenital malformations are more prevalent in male than female cats. Congenital malformations in both species can occur as isolated defects, which is most often the case, or in various combinations.

The prevalence of congenital defects is higher in purebred animals than in mixed-breed animals. In some studies a polygenic inheritance pattern has been suggested, although there is more recent focus on a single major gene effect influenced by other modifying genes. Recognized breed predispositions are listed in Table 5-1; animals of other breeds can also be affected with any of these defects as well.

# EXTRACARDIAC ARTERIOVENOUS SHUNT

The most common congenital arteriovenous shunt is PDA. Rarely, similar hemodynamic and clinical abnormalities are caused by an aorticopulmonary window (a communication between the ascending aorta and pulmonary artery) or some other functionally similar communication in the hilar region.

#### **PATENT DUCTUS ARTERIOSUS**

# **Etiology and Pathophysiology**

Functional closure of the ductus arteriosus normally occurs within hours after birth and is followed by structural changes that occur over several months, which cause permanent closure. The ductal wall in animals with an inherited PDA is histologically abnormal and unable to constrict. When the ductus fails to close, blood shunts through it from the descending aorta into the pulmonary artery. Shunting occurs during both systole and diastole because aortic pressure normally is higher than pulmonic pressure throughout the cardiac cycle. This left-to-right shunt causes a volume overload of the pulmonary circulation, left atrium (LA), and left ventricle (LV). The shunt volume is directly related to the pressure difference (gradient) between the two circulations and the diameter of the ductus.

Hyperkinetic arterial pulses are characteristic of PDA. Blood runoff from the aorta into the pulmonary system allows diastolic aortic pressure to decrease below normal.

TABLE 5-1

# Breed Predispositions for Congenital Heart Disease

DISEASE	BREED	
Patent ductus arteriosus	Maltese, Pomeranian, Shetland Sheepdog, English Springer Spaniel, Keeshond, Bichon Frise, Toy and Miniature Poodles, Yorkshire Terrier, Collie, Cocker Spaniel, German Shepherd Dog; Chihuahua, Kerry Blue Terrier, Labrador Retriever, Newfoundland; female > male	
Subaortic stenosis	Newfoundland, Golden Retriever, Rottweiler, Boxer, German Shepherd Dog, English Bulldog, Great Dane, German Short-Haired Pointer, Bouvier des Flandres, Samoyed	
Pulmonic stenosis	Bulldog (male > female), Mastiff, Samoyed, Miniature Schnauzer, West Highland White Terrier, Cocker Spaniel, Beagle, Airedale Terrier, Boykin Spaniel, Chihuahua, Scottish Terrier, Boxer, Fox Terrier(?)	
Ventricular septal defect	English Bulldog, English Springer Spaniel, Keeshond; cats	
Atrial septal defect	Samoyed, Doberman Pinscher, Boxer	
Tricuspid dysplasia	Labrador Retriever, German Shepherd Dog, Boxer, Weimaraner, Great Dane, Old English Sheepdog, Golden Retriever; other large breeds; (male > female?)	
Mitral dysplasia	Bull Terrier, German Shepherd Dog, Great Dane, Golden Retriever, Newfoundland, Mastiff, Rottweiler(?); cats; (male > female)	
Tetralogy of Fallot	Keeshond, English Bulldog	
Persistent right aortic arch	German Shepherd Dog, Great Dane, Irish Setter	

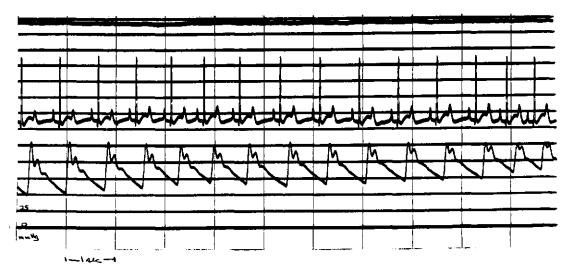

FIG 5-2

Continuous femoral artery pressure recording during surgical ligation of a patent ductus arteriosus in a Poodle. The wide pulse pressure (left side of trace) narrows as the ductus is closed (right side of trace). Diastolic arterial pressure rises because blood runoff into the pulmonary artery is curtailed. (Courtesy Dr. Dean Riedesel.)

The widened pulse pressure (systolic minus diastolic pressure) causes palpably stronger arterial pulses (Fig. 5-2),

Compensatory mechanisms (e.g., increased heart rate, volume retention) maintain adequate systemic blood flow. However, the l.V is subjected to a great hemodynamic burden, especially when the ductus is large, because the increased stoke volume is pumped into the relatively high pressure aorta. l.V and mitral annulus dilation in turn cause mitral regurgitation and further volume overload. Excess fluid retention, declining myocardial contractility

stemming from the chronic volume overload, and arrhythmias contribute to the development of congestive heart failure (CHF).

In some cases, excessive pulmonary blood flow leads to pulmonary vascular changes, increased resistance, and pulmonary hypertension (see p. 109). If pulmonary artery pressure rises to equal aortic pressure, very little blood shunting occurs. However, if pulmonary artery pressure exceeds aortic pressure, shunt reversal (right-to-left flow) occurs. Approximately 15% of dogs with inherited PDA develop a reversed

shunt; female Cocker Spaniels may be at increased risk for reversed PDA.

#### **Clinical Features**

A left-to-right shunting PDA (discussed here) is by far the most common form; clinical features of reversed PDA are described on p. 110. The prevalence of PDA is higher in certain breeds of dogs, and a polygenic inheritance pattern is thought to be responsible. The prevalence is approximately three times greater in female than male dogs. Reduced exercise ability, tachypnea, or cough is present in some cases, but many animals are asymptomatic when first diagnosed. Typical findings include a continuous murmur heard best high at the left base (see p. 9), often with a precordial thrill, hyperkinetic (bounding, "waterhammer") arterial pulses, and pink mucous membranes.

# Diagnosis

Radiographs usually show cardiac clongation (left heart dilation), left atrial and auricular enlargement, and pulmonary overcirculation (Table 5-2). A bulge often is evident in the descending aorta ("ductus bump") or main pulmonary trunk, or both (Fig. 5-3). The triad of all three bulges (i.e., pulmonary trunk, aorta, and left auricle), located in that order from the 1 to 3 o'clock position on a dorsoventral (DV) radiograph, is a classic finding but not always seen. There is also evidence of pulmonary edema in animals with left-sided heart failure. Characteristic ECG findings include wide P waves, tall R waves, and often deep Q waves in leads II, aVF, and CV<sub>6</sub>LL. Changes in the ST-T segment secondary

to LV enlargement may occur. However, the ECG is normal in some animals with PDA.

Echocardiography also shows left heart enlargement and pulmonary trunk dilation. LV fractional shortening can be normal or decreased, and the E point-septal separation is often increased. The ductus itself may be difficult to visualize because of its location between the descending aorta and pulmonary artery. Views from the cranial left parasternal position are useful. Doppler interrogation documents continuous, turbulent flow into the pulmonary artery (Fig. 5-4). The maximum aortic-to-pulmonary artery pressure gradient should be estimated. Cardiac catheterization is generally unnecessary for diagnosis, although it is important during interventional procedures. Catheterization findings include higher oxygen content in the pulmonary artery compared with the right ventricle (oxygen "step-up") and a wide aortic pressure pulse. Angiocardiography shows left-to-right shunting through the ductus (see Fig. 5-3, *C*).

# **Treatment and Prognosis**

Closure of the left-to-right ductus, usually performed as soon as is feasible, is recommended by either a transcatheter or surgical occlusion method. Surgical ligation is successful in most cases, although a perioperative mortality of about 10% has been reported. Patient age or weight does not appear to affect the outcome of surgery. Several methods of transcatheter PDA occlusion are available. These involve placing a vascular occluding device (e.g., the Amplatz canine ductal occluder) or wire coils with attached thrombogenic tufts within the ductus. Vascular access is usually via the femoral

TABLE 5-2

Radiographic Findings In Common Congenital Heart Defects

DEFECT	HEART	PULMONARY VESSELS	OTHER
PDA	LAE, LVE; left auricular bulge; ± increased cardiac width	Overcirculated	Bulge(s) in descending aorta + pulmonary trunk; ± pulmonary edema
SAS	± LAE, LVE	Normal	Wide cranial cardiac waist (dilated ascending aorta)
PS	RAE, RVE; reverse D	Normal to undercirculated	Pulmonary trunk bulge
VSD	LAE, LVE; ± RVE	Overcirculated	± Pulmonary edema; ± pulmonary trunk bulge (large shunts)
ASD	RAE, RVE	± Overcirculated	± Pulmonary trunk bulge
T dys	RAE, RVE; ± globoid shape	Normal	Caudal cava dilation; ± pleural effusion, ascites, hepatomegaly
M dys	LAE, LVE	± Venous hypertension	± Pulmonary edema
TofF	RVE, RAE; reverse D	Undercirculated; ± prominent bronchial vessels	Normal to small pulmonary trunk; ± cranial aortic bulge on lateral view
PRAA	Normal	Normal	Focal leftward and ventral tracheal deviation ± narrowing cranial to heart; wide cranial mediastinum; megaesophagus; (± aspiration pneumonia)

ASD, Atrial septal defect; LAE, left atrial enlargement; LVE, left ventricular enlargement; M dys, mitral dysplasia; PDA, patent ductus arteriosus; PS, pulmonic stenosis; RVE, right ventricular enlargement; RAE, right atrial enlargement; SAS, subaortic stenosis; T dys, tricuspid dysplasia; T of F, tetralogy of Fallot; VSD, ventricular septal defect.

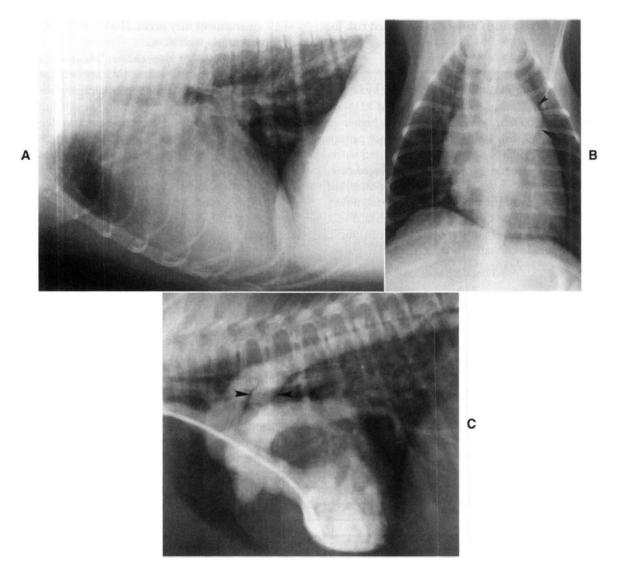

FIG 5-3
Lateral (A) and dorsoventral (DV) (B) radiographs from a dog with a patent ductus arteriosus. Note the large and elongated heart and prominent pulmonary vasculature. A large bulge is seen in the descending aorta on the DV view (arrowheads in B).

C, Angiocardiogram obtained using a left ventricular injection outlines the left ventricle, aorta, patent ductus (arrowheads), and pulmonary artery.

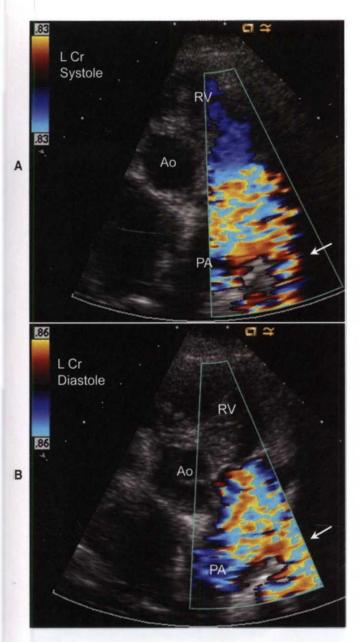

artery, although some have used a venous approach to the ductus. Where available, transcatheter PDA occlusion offers a much less invasive alternative to surgical ligation. Complications can occur (including aberrant coil embolization and residual ductal flow, among others), and not all cases are suitable for transcatheter occlusion. A normal life span can be expected after uncomplicated ductal closure. The concurrent mitral regurgitation usually resolves after ductus ligation or occlusion if the valve is structurally normal.

Animals with CHF are treated with furosemide, an angiotensin-converting enzyme inhibitor (ACEI), rest, and dietary sodium restriction (see Chapter 3). Because contractility tends to decline over time, pimobendan or digoxin may be indicated as well. Arrhythmias are treated as necessary.

If the ductus is not closed, prognosis depends on its size and the level of pulmonary vascular resistance. CHF is the eventual outcome for most patients that do not undergo ductal closure. More than 50% of affected dogs die within the first year. In animals with pulmonary hypertension and shunt reversal, ductal closure is contraindicated because the ductus acts as a "pop-off" valve for the high right-sided pressures. Ductal ligation in animals with reversed PDA produces no improvement and can lead to right ventricular (RV) failure.

# **VENTRICULAR OUTFLOW OBSTRUCTION**

Ventricular outflow obstruction can occur at the semilunar valve, just below the valve (subvalvular), or above the valve in the proximal great vessel (supravalvular). SAS and PS are most common in dogs and cats. Stenotic lesions impose a

Continuous turbulent flow into the pulmonary artery from the area of the patent ductus (arrow) is illustrated by systolic (A) and diastolic (B) color flow Doppler frames from the left cranial parasternal position, in an adult female Springer Spaniel. Ao, Ascending aorta; PA, main pulmonary artery; RV, right ventricle.

pressure overload on the affected ventricle, requiring higher systolic pressure as well as a slightly longer time to eject blood across the narrowed outlet. This generates a systolic pressure gradient across the stenosis because pressure downstream of the stenosis is normal. The magnitude of this gradient is related to the severity of the obstruction.

Concentric myocardial hypertrophy typically develops in response to a systolic pressure overload; some dilation of the affected ventricle can also occur. Ventricular hypertrophy can impede diastolic filling (by increasing ventricular stiffness) or lead to secondary AV valve regurgitation. Heart failure results when ventricular diastolic and atrial pressures are elevated. Cardiac arrhythmias can contribute to the onset of CHF. Furthermore, the combination of outflow obstruction, paroxysmal arrhythmias, and/or inappropriate bradycardia reflexly triggered by ventricular baroreceptor stimulation can result in signs of low cardiac output. These are often associated with severe outflow tract obstruction and include exercise intolerance, syncope, and sudden death.

#### SUBAORTIC STENOSIS

# **Etiology and Pathophysiology**

Subvalvular narrowing caused by a fibrous or fibromuscular ring is the most common type of aortic stenosis in dogs. Certain larger breeds of dog are predisposed to this defect. SAS is thought to be inherited as an autosomal dominant trait with modifying genes that influence its phenotypic expression. SAS also occurs in cats; supravalvular lesions have been reported in this species as well.

The spectrum of SAS severity varies widely; three grades of SAS have been described in Newfoundland dogs. The mildest (grade I) is associated with no clinical signs or murmur and only subtle subaortic fibrous tissue ridging seen on postmortem examination. Moderate (grade II) SAS consists of mild clinical and hemodynamic evidence of the disease, with an incomplete fibrous ring below the aortic valve found at postmortem. Dogs with grade III SAS have severe disease and a complete fibrous ring around the outflow tract. Some cases have an elongated, tunnel-like obstruction. There may also be malformations of the mitral valve apparatus. Outflow tract narrowing and dynamic obstruction with or without a discrete subvalvular ridge have also been noted in Golden Retrievers. A component of dynamic LV outflow tract obstruction may be important in other dogs as well.

The obstructive lesion of SAS develops during the first several months of life, and there may be no audible murmur at an early age. In some dogs no murmur is detected until 1 to 2 years of age, and the obstruction may continue to worsen beyond that. Murmur intensity usually increases with exercise or excitement. Because of such factors, as well as the presence of physiologic murmurs in some animals, definitive diagnosis and genetic counseling to breeders can be difficult.

The severity of the stenosis determines the degree of LV pressure overload and resulting concentric hypertrophy. Coronary perfusion is easily compromised in animals with severe SAS and left ventricular hypertrophy. Capillary density may become inadequate as hypertrophy progresses, and high systolic wall tension with coronary narrowing can cause systolic flow to be reversed in small coronary arteries. These factors contribute to the development of myocardial ischemia and fibrosis. Clinical sequelae include arrhythmias, syncope, and sudden death. Many animals with SAS also have aortic or mitral valve regurgitation because of related malformations or secondary changes; this imposes a volume overload on the LV. Left-sided CHF develops in some cases. Animals with SAS are thought to be at higher risk for devel-

oping aortic valve endocarditis because of jet lesion injury to the underside of the valve (see p. 121 and Figure 6-4).

#### **Clinical Features**

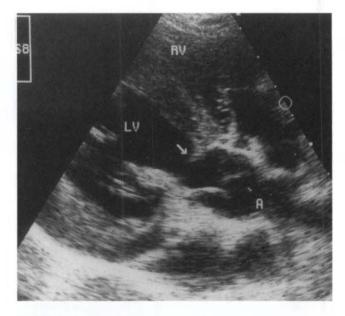

Historical signs of fatigue, exercise intolerance or exertional weakness, syncope, or sudden death occur in about a third of dogs with SAS. Low-output signs can result from severe outflow obstruction, tachyarrhythmias or sudden reflex bradycardia, and hypotension resulting from the activation of ventricular mechanoreceptors. Left-sided CHF can develop, usually in conjunction with concurrent mitral or aortic regurgitation, other cardiac malformations, or acquired endocarditis. Dyspnea is the most commonly reported sign in cats with SAS.

Characteristic physical examination findings in dogs with moderate-to-severe stenosis include weak and late-rising femoral pulses (pulsus parvus et tardus) and a precordial thrill low at the left heartbase. A harsh systolic ejection murmur is heard at or below the aortic valve area on the left hemithorax. This murmur often radiates equally or more loudly to the right heartbase because of the orientation of the aortic arch. The murmur frequently is heard over the carotid arteries, and it may even radiate to the calvarium. In mild cases a soft, poorly radiating ejection murmur at the left and sometimes right heartbase may be the only abnormality found on physical examination. Functional aortic stenosis murmurs that are not associated with SAS are common in Greyhounds and other sight hounds. Aortic regurgitation can produce a diastolic murmur at the left base or may be inaudible. Severe aortic regurgitation can increase the arterial pulse strength. There may be evidence of pulmonary edema or arrhythmias.

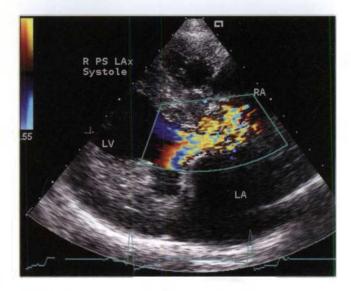

# **Diagnosis**

Radiographic abnormalities (see Table 5-2) can be subtle, especially in dogs and cats with mild SAS. The LV can appear normal or enlarged. Poststenotic dilation in the ascending aorta can cause a prominent cranial waist in the cardiac silhouette (especially on a lateral view) and cranial mediastinal widening. The ECG is often normal, although evidence of LV hypertrophy (left axis deviation) or enlargement (tall complexes) can be present. Depression of the ST segment in leads II and aVF can occur from secondary myocardial ischemia or to hypertrophy; exercise induces further ischemic ST-segment changes in some animals. Ventricular tachyarrhythmias are common.

Echocardiography reveals the extent of LV hypertrophy and subaortic narrowing. A discrete tissue ridge below the aortic valve is evident in many animals with moderate-to-severe disease (Fig. 5-5). Premature closure of the aortic valve, systolic anterior motion of the anterior mitral leaflet, and increased LV subendocardial echogenicity (probably from fibrosis) are common in animals with severe obstruction. Ascending aorta dilation, aortic valve thickening, and LA enlargement with hypertrophy may also be seen. In mildly affected animals 2-D and M-mode findings may be unremarkable. Doppler echocardiography reveals systolic

Echocardiogram from a 6-month-old German Shepherd Dog with severe subaortic stenosis. Note the discrete ridge of tissue (arrow) below the aortic valve, creating a fixed outflow tract obstruction. A, Aorta; LV, left ventricle; RV, right ventricle.

Color flow Doppler frame of the left ventricular outflow region in systole from a 2-year-old female Rottweiler with severe subaortic stenosis. Note the turbulent flow pattern originating below the aortic valve, as well as the thickened septum, papillary muscle, and left ventricular free wall. Right parasternal long axis view; Ao, aorta; LA, left atrium; LV, left ventricle; RA, right atrium.

turbulence originating below the aortic valve and extending into the aorta, as well as high peak systolic outflow velocity (Fig. 5-6). Some degree of aortic or mitral regurgitation is common. Spectral Doppler studies are used to estimate the stenosis severity. Doppler-estimated systolic pressure gradients in unanesthetized animals are usually 40% to 50%

higher than those recorded during cardiac catheterization under anesthesia. Severe SAS is associated with peak estimated gradients >100 to 125 mm Hg. The LV outflow tract should be interrogated from more than one position to achieve the best possible alignment with blood flow. The subcostal (subxiphoid) position usually yields the highestvelocity signals, although the left apical position is optimal in some animals. The Doppler-estimated aortic outflow velocity may be only equivocally high in animals with mild SAS, especially with suboptimal Doppler beam alignment. With optimal alignment, aortic root velocities of <1.7 m/sec are typical in normal unsedated dogs; velocities over ~2.25 m/ sec are generally considered abnormal. Peak velocities in the equivocal range between these values may indicate the presence of mild SAS, especially if there is other evidence of disease, such as disturbed flow in the outflow tract or ascending aorta and aortic regurgitation. This is mainly of concern when selecting animals for breeding. In some breeds (e.g., Greyhound, Boxer, Golden Retriever), outflow velocities in this equivocal range (1.8-2.25 m/sec) are common. This may reflect breed-specific variation in LV outflow tract anatomy or response to sympathetic stimulation, rather than SAS. A limitation of using the estimated pressure gradient to assess outflow obstruction severity is that this gradient depends on blood flow. Factors causing sympathetic stimulation and increased cardiac output (e.g., excitement, exercise, fever) will increase outflow velocities, whereas myocardial failure, cardiodepressant drugs, and other causes of reduced stroke volume will decrease recorded velocities. Cardiac catheterization and angiocardiography are rarely used now to diagnose or quantify SAS, except in conjunction with balloon dilation of the stenotic area.

# Treatment and Prognosis

Several palliative surgical techniques have been used in dogs with severe SAS, with limited success. Cardiopulmonary bypass and open-heart surgery are necessary to reach the lesion directly. Although resection of the stenotic area can significantly reduce the LV systolic pressure gradient and possibly improve exercise ability, a long-term survival advantage appears lacking. Transvascular balloon dilation of the stenotic area reduces the measured gradient in some dogs, although narrowing may partially recur. Likewise, no survival benefit has been documented with this procedure.

Medical therapy with a  $\beta$ -blocker is advocated in patients with moderate to severe SAS to reduce myocardial oxygen demand and minimize the frequency and severity of arrhythmias. Animals with a high pressure gradient, marked ST-segment depression, frequent ventricular premature beats, or a history of syncope may be more likely to benefit from this therapy. Whether  $\beta$ -blockers prolong survival is unclear. Exercise restriction is advised for animals with moderate-to-severe SAS. Prophylactic antibiotic therapy is recommended for animals with SAS before the performance of any procedures with the potential to cause bacteremia (e.g., dentistry).

The prognosis in dogs and cats with severe stenosis (catheterization pressure gradient >80 mm Hg or Doppler gradi-

ent >100-125 mm Hg) is guarded. More than half of dogs with severe SAS die suddenly within their first 3 years. The overall prevalence of sudden death in dogs with SAS appears to be just over 20%. Infective endocarditis and CHF may be more likely to develop after 3 years of age. Atrial and ventricular arrhythmias and worsened mitral regurgitation are complicating factors. Dogs with mild stenosis (e.g., catheterization gradient <35 mm Hg or Doppler gradient <60-70 mm Hg) are more likely to survive longer and without clinical signs.

#### **PULMONIC STENOSIS**

# **Etiology and Pathophysiology**

PS is more common in small breeds of dogs. Some cases of valvular PS result from simple fusion of the valve cusps, but valve dysplasia is more common. Dysplastic valve leaflets are variably thickened, asymmetric, and partially fused, with a hypoplastic valve annulus. Right ventricular pressure overload produces right ventricle (RV) hypertrophy as well as secondary dilation. Severe ventricular hypertrophy promotes myocardial ischemia and its sequelae. Excessive muscular hypertrophy below the valve (infundibular area) can create a dynamic subvalvular component to the stenosis. Other variants of PS, including supravalvular stenosis and RV muscular partition (double chamber RV) occur rarely.

High-velocity blood flow across the stenotic orifice creates turbulence leading to poststenotic dilation in the main pulmonary trunk. Right atrial dilation from secondary tricuspid insufficiency and high RV filling pressure predisposes to atrial tachyarrhythmias and CHF. The combination of PS and a patent foramen ovale or ASD can allow right-to-left shunting at the atrial level, but this is rare in dogs and cats.

A single anomalous coronary artery has been described in some Bulldogs and Boxers with PS and is thought to contribute to the outflow obstruction. In such cases, palliative surgical procedures and balloon valvuloplasty may cause death secondary to transection or avulsion of the major left coronary branch.

#### **Clinical Features**

Many dogs with PS are asymptomatic when diagnosed, although right-sided CHF or a history of exercise intolerance or syncope may exist. Clinical signs may not develop until the animal is several years old, even in those with severe stenosis. Physical examination findings characteristic of moderate-to-severe stenosis include a prominent right precordial impulse; a thrill high at the left base; normal to slightly diminished femoral pulses; pink mucous membranes; and, in some cases, jugular pulses. A systolic ejection murmur is heard best high at the left base on auscultation. The murmur can radiate cranioventrally and to the right in some cases but usually is not heard over the carotid arteries. An early systolic click is sometimes identified; this probably is caused by abrupt checking of a fused valve at the onset of ejection. A murmur of tricuspid insufficiency or arrhythmias can be heard in some cases.

# **Diagnosis**

Radiographic findings typically seen in animals with PS are outlined in Table 5-2. Marked RV hypertrophy shifts the cardiac apex dorsally and to the left. The heart may appear as a "reverse D" shape on a DV or ventrodorsal (VD) view. A variably sized pulmonary trunk bulge (poststenotic dilation) is best seen at the 1 o'clock position on a DV or VD view (Fig. 5-7). The size of the poststenotic dilation does not correlate with the severity of the pressure gradient. A dilated caudal vena cava is also seen in some animals.

ECG changes are more common in patients with moderate to severe stenosis. These include an RV hypertrophy pattern, right axis deviation, and sometimes an RA enlargement pattern (P pulmonale) or tachyarrhythmias. Echocar-

diographic findings characteristic of moderate-to-severe stenosis include RV hypertrophy and enlargement. The interventricular septum often appears flattened as high RV pressure pushes it toward the left (Figure 5-8, A). RA enlargement is often seen as well. A thickened, asymmetrical, or otherwise malformed pulmonic valve usually can be identified (Fig. 5-8, B), although the outflow area may be narrow and difficult to visualize clearly. Poststenotic dilation of the main pulmonary trunk is expected. Pleural effusion and marked right heart dilation often accompany secondary CHF. Paradoxical septal motion is likely in such cases as well. Doppler evaluation along with anatomic findings provides an estimate of PS severity. Cardiac catheterization and angiocardiography also can be used to assess the pressure gradient

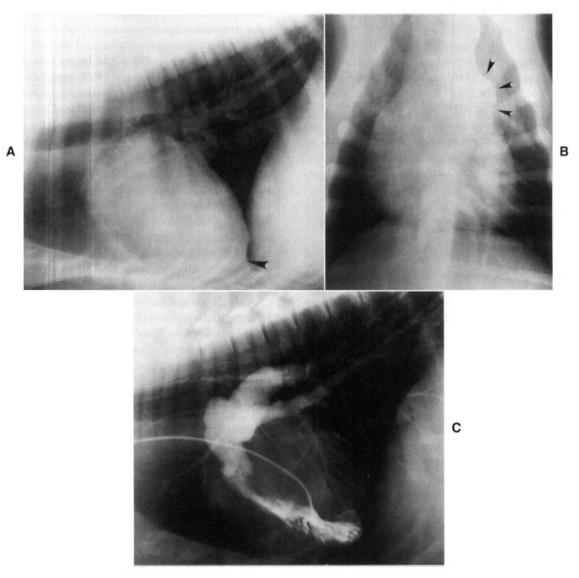

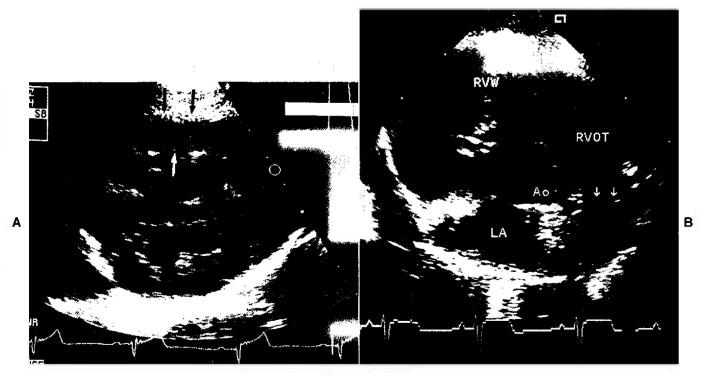

FIG 5-7
Lateral (A) and dorsoventral (DV) (B) radiographs from a dog with pulmonic stenosis, showing right ventricular enlargement (apex elevation on lateral view [arrowhead in A] and reverse D configuration on DV view) along with a pulmonary trunk bulge (arrowheads in B) seen on a DV view. C, Angiocardiogram using a selective right ventricular injection demonstrates poststenotic dilation of the main pulmonary trunk and pulmonary arteries. The thickened pulmonic valve is closed in this diastolic frame.

Echocardiograms from two dogs with severe pulmonic stenosis. (A) Right parasternal short-axis view at the ventricular level in a 4-month-old male Samoyed shows right ventricular hypertrophy (arrows) and enlargement; high right ventricular pressure flattens the septum toward the left in this diastolic frame. (B) Thickened, partially fused leaflets of the malformed pulmonary valve (arrows) are seen in a 5-month-old male Pomeranian. Ao, Aortic root; LA, left atrium; RVOT, right ventricular outflow tract; RVW, right ventricular wall.

across the stenotic valve, the right heart filling pressure, and other anatomic features. Doppler-estimated systolic pressure gradients in unanesthetized animals are usually 40% to 50% higher than those recorded during cardiac catheterization. PS is generally considered mild if the Doppler-derived gradient is <50 mm Hg and severe if it is >80 to 100 mm Hg.

# **Treatment and Prognosis**

Balloon valvuloplasty is recommended for palliation of severe (and sometimes moderate) stenosis, especially if infundibular hypertrophy is not excessive. This procedure reduces or eliminates clinical signs and appears to improve long-term survival in severely affected animals. Balloon valvuloplasty, done in conjunction with cardiac catheterization, involves passing a specially designed balloon catheter across the valve and inflating the balloon to enlarge the stenotic orifice. The procedure is most successful in dogs with simple fusion of the pulmonic valve cusps. Dysplastic valves are more difficult to dilate effectively, but good results are possible in some cases. Various surgical procedures also have been used to palliate moderate-to-severe PS in dogs. Balloon valvuloplasty generally is attempted before a surgical procedure because it is less risky. Animals with a single anomalous coronary artery should not undergo balloon or surgical dilation procedures. Coronary anatomy can be verified using echocardiography or angiography.

Exercise restriction is generally advised for animals with moderate-to-severe stenosis. A  $\beta$ -blocker may be helpful, especially in those with prominent RV infundibular hypertrophy. Signs of CHF are managed medically (see Chapter 3). The prognosis in patients with PS is variable and depends on the severity of the lesion. Life span can be normal in those with mild PS, whereas animals with severe PS often die within 3 years of diagnosis. Sudden death or the onset of CHF is common. The prognosis is considerably worse in animals with tricuspid regurgitation, atrial fibrillation or other tachyarrhythmias, or CHF.

# INTRACARDIAC SHUNT

Blood flow volume across an intracardiac shunt depends on the size of the defect and the pressure gradient across it. In most cases, flow direction is from left to right, causing pulmonary overcirculation. Compensatory increases in blood volume and cardiac output occur in response to the partial diversion of blood away from the systemic circulation. A volume overload is imposed on the side of the heart doing the most work. If right heart pressures increase as a result of pulmonary hypertension or a concurrent PS, shunt flow may equilibrate or reverse (i.e., become right-to-left).

#### **VENTRICULAR SEPTAL DEFECT**

# **Etiology and Pathophysiology**

Most VSDs are located in the membranous part of the septum, just below the aortic valve and beneath the septal tricuspid leaflet. VSDs sporadically occur in other septal locations also. A VSD may be accompanied by other AV septal (endocardial cushion) malformations, especially in cats. Usually, VSDs produce a volume overload on the lungs, LA, LV, and RV outflow tract. Small defects may be clinically unimportant. Moderate-to-large defects tend to cause left heart dilation and can lead to left-sided CHF. A very large VSD causes both ventricles to function as a common chamber and induces RV dilation and hypertrophy. Pulmonary hypertension secondary to overcirculation is more likely to develop in animals with a large shunt. Some animals with VSD also have aortic regurgitation, with diastolic prolapse of a valve leaflet. Presumably this occurs because the deformed septum provides inadequate anatomic support for the aortic root. Aortic regurgitation places an additional volume load on the LV.

#### **Clinical Features**

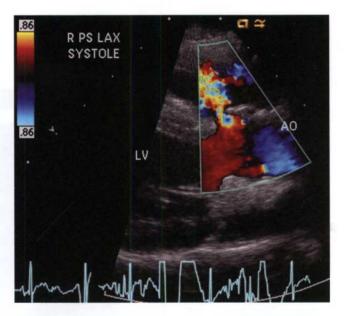

The most common clinical manifestations of VSD are exercise intolerance and signs of left-sided CHF. Many animals are asymptomatic at the time of diagnosis. The characteristic auscultatory finding is a holosystolic murmur, heard loudest at the cranial right sternal border (which corresponds to the direction of shunt flow). A large shunt volume can produce a murmur of relative or functional PS (systolic ejection murmur at the left base). With concurrent aortic regurgitation, the corresponding diastolic decrescendo murmur is heard at the left base.

# **Diagnosis**

Radiographic findings associated with VSD vary with thesize of the defect and the shunt volume (see Table 5-2). Large shunts cause left heart enlargement and pulmonary overcirculation. However, large shunts that increase pulmonary vascular resistance and pressure lead to RV enlargement. A large shunt volume (with or without pulmonary hypertension) also can increase main pulmonary trunk size.

The ECG may be normal or suggest LA or LV enlargement. In some cases, disturbed intraventricular conduction is suggested by "fractionated" or splintered QRS complexes. An RV enlargement pattern usually indicates a very large defect, pulmonary hypertension, or a concurrent RV outflow tract obstruction, although sometimes a right bundle-branch block causes this pattern.

Echocardiography reveals left heart dilation (with or without RV dilation) when the shunt is large. The defect often can be visualized just below the aortic valve in the right parasternal long-axis LV outflow view. The septal tricuspid leaflet is located to the right of the defect. Because echo "dropout" at the thin membranous septum can mimic a VSD, the area of a suspected defect should be visualized in

Color flow Doppler frame in systole showing turbulent flow (from left to right) through a small membranous ventricular septal defect just below the aortic root in a 1-year-old male terrier. Right parasternal long axis view; AO, aortic root; LV, left ventricle.

more than one plane. Supporting clinical evidence and a murmur typical of a VSD also should be present before the diagnosis is made. Doppler (or echo-contrast) studies usually demonstrate the shunt flow (Fig. 5-9).

Cardiac catheterization, oximetry, and angiocardiography allow measurement of intracardiac pressures, indicate the presence of an oxygen step-up at the level of the RV outflow tract, and show the pathway of abnormal blood flow.

# **Treatment and Prognosis**

A small-to-moderate defect usually allows a relatively normal life span. In some cases, the defect closes spontaneously within the first 2 years of life. Closure can result from myocardial hypertrophy around the VSD or a seal formed by the septal tricuspid leaflet or a prolapsed aortic leaflet. Left-sided CHF is more likely in animals with a large septal defect, although pulmonary hypertension with shunt reversal develops in some instead, usually at an early age.

Definitive therapy for VSD usually requires cardiopulmonary bypass or hypothermia and intracardiac surgery, although transcatheter delivery of an occlusion device may be possible in some cases. Large left-to-right shunts are sometimes palliated by surgically placing a constrictive band around the pulmonary trunk to create a mild supravalvular PS. This raises RV systolic pressure in response to the increased outflow resistance. Consequently, less blood shunts from LV to RV. An excessively tight band can cause right-to-left shunting (functionally analogous to a T of F), however. Left-sided CHF is managed medically. Palliative surgery

should not be attempted in the presence of pulmonary hypertension and shunt reversal.

# ATRIAL SEPTAL DEFECT

# **Etiology and Pathophysiology**

Several types of ASD exist. Those located in the region of the fossa ovalis (ostium secundum defects) are more common in dogs. An ASD in the lower interatrial septum (ostium primum defect) is likely to be part of the AV septal (endocardial cushion or common AV canal) defect complex, especially in cats. Sinus venosus—type defects are rare; these are located high in the atrial septum near the entry of the cranial vena cava. Animals with ASD commonly have other cardiac malformations as well. In most cases of ASD, blood shunts from LA to RA and results in a volume overload to the right heart. However, if PS or pulmonary hypertension is present, right-to-left shunting and cyanosis may occur.

# **Clinical Features**

The clinical history in animals with an ASD is usually rather nonspecific. Physical examination findings associated with an isolated ASD are often unremarkable, although large left-to-right shunts can cause a murmur of relative PS. Fixed splitting (i.e., with no respiratory variation) of the second heart sound  $(S_2)$  is the classic auscultatory finding. Rarely, a soft diastolic murmur of relative tricuspid stenosis might be audible.

# Diagnosis

Right heart enlargement, with or without pulmonary trunk dilation, is found radiographically in patients with severe shunts (see Table 5-2). The pulmonary circulation may appear to be increased unless pulmonary hypertension has developed. Left heart enlargement is not seen unless another defect, such as mitral insufficiency, is present. The ECG may be normal or show evidence of RV and RA enlargement. Cats with an AV septal defect may have RV enlargement and a left axis deviation.

Echocardiography is likely to show RA and RV dilation, with or without paradoxical interventricular septal motion. Large ASDs can be visualized. Care must be taken not to confuse the thinner fossa ovalis region of the interatrial septum with an ASD because echo dropout also occurs here. Doppler echocardiography allows identification of smaller shunts that cannot be clearly visualized on 2-D exam, but venous inflow streams may complicate this. Cardiac catheterization shows an oxygen step-up at the level of the RA. Abnormal flow through the shunt may be evident after the injection of contrast material into the pulmonary artery.

# **Treatment and Prognosis**

Large shunts can be treated surgically, similarly to VSDs. Otherwise, animals are managed medically if CHF develops. The prognosis is variable and depends on shunt size, concurrent defects, and the level of pulmonary vascular resistance.

# ATRIOVENTRICULAR VALVE MALFORMATION

# MITRAL DYSPLASIA

Congenital malformations of the mitral valve apparatus include shortened or overly elongated chordae tendineae, direct attachment of the valve cusp to a papillary muscle, thickened or cleft or shortened valve cusps, prolapse of valve leaflets, upwardly displaced or malformed papillary muscles, and excessive dilation of the valve annulus. Mitral valve dysplasia (MD) is most common in large-breed dogs and also occurs in cats. Valvular regurgitation is the predominant functional abnormality, and it may be severe; the pathophysiology and sequelae resemble those of acquired mitral regurgitation (see p. 121). Mitral valve stenosis is uncommon. Obstruction to ventricular filling increases LA pressure and can precipitate the development of pulmonary edema. Mitral regurgitation usually accompanies stenosis.

The clinical signs seen in patients with MD are similar to those in dogs with degenerative mitral valve disease, except for the younger patient age. Reduced exercise tolerance, respiratory signs of left-sided CHF, inappetence, and atrial arrhythmias (especially atrial fibrillation) are common in affected animals. Mitral regurgitation typically causes a systolic murmur heard best at the left apex.

The radiographic, ECG, echocardiographic, and catheterization findings are similar to those found in patients with acquired mitral insufficiency. Echocardiography can depict the specific mitral apparatus malformations as well as the degree of chamber enlargement and functional changes.

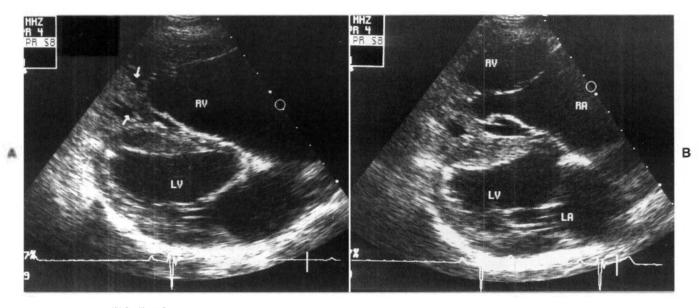

Therapy consists of medical management for CHF. Animals with mild to moderate mitral valve dysfunction may do well clinically for years. However, for those with severe mitral regurgitation or stenosis, the prognosis is poor. Surgical valve reconstruction or replacement may be possible in some cases.

#### TRICUSPID DYSPLASIA

Animals with tricuspid dysplasia (TD) have malformations of the tricuspid valve and related structures that are similar to those of MD. The tricuspid valve can be displaced ventrally into the ventricle (an Ebsteinlike anomaly) in some cases; ventricular preexcitation may be more likely in these animals. Tricuspid dysplasia is identified most frequently in large-breed dogs, particularly in Labrador Retrievers, and in males.

The pathophysiologic features of TD are the same as those of acquired tricuspid regurgitation. Severe cases result in marked enlargement of the right heart chambers. Progressive increase in RA and RV end-diastolic pressures eventually result in right-sided CHF. Tricuspid stenosis is rare.

The historical signs and clinical findings likewise are similar to those of degenerative tricuspid disease. Initially, the animal may be asymptomatic or mildly exercise intolerant. However, exercise intolerance, abdominal distention resulting from ascites, dyspnea resulting from pleural effusion, anorexia, and cardiac cachexia often develop. The

Right parasternal long-axis echo images from a 1-year-old male Labrador Retriever with tricuspid valve dysplasia in diastole (**A**) and systole (**B**). The valve annulus appears to be ventrally displaced; the leaflet tips are tethered to a malformed, wide papillary muscle (arrows in **A**). Wide leaflet tip separation in systole (**B**) caused severe tricuspid regurgitation and clinical congestive heart failure. LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

murmur of tricuspid regurgitation is characteristic but not always clearly audible. Jugular pulsations are common. Additional signs that accompany CHF include jugular vein distention, muffled heart and lung sounds, and ballotable abdominal fluid.

Radiographs demonstrate RA and RV enlargement. The round appearance of the heart shadow in some cases is similar to that seen in patients with pericardial effusion or dilated cardiomyopathy. A distended caudal vena cava, pleural or peritoneal effusion, and hepatomegaly are common.

RV and occasionally RA enlargement patterns are seen on ECG. A splintered QRS complex configuration may be seen. Atrial fibrillation or another atrial tachyarrhythmias occur commonly. Some patients exhibit signs of ventricular preexcitation.

Echocardiography reveals right heart dilation, which can be massive. Valve apparatus malformations also may be clear in several views (Fig. 5-10), although the left apical four-chamber view is especially useful. Intracardiac electrocardiography is necessary to confirm an Ebstein's anomaly, which is suggested by ventral displacement of the tricuspid valve annulus. A ventricular electrogram recorded on the RA side of the valve is diagnostic, although this technique is rarely done in the clinic.

CHF and arrhythmias are managed medically. Periodic thoracocentesis may be needed in animals with pleural effusion that cannot be controlled with medication and diet. The prognosis is guarded to poor, especially when cardiomegaly is marked. Nevertheless, some dogs survive for several years. Balloon dilation has been used successfully to treat tricuspid stenosis.

# CARDIAC ANOMALIES CAUSING CYANOSIS

Malformations that allow deoxygenated blood to reach the systemic circulation result in hypoxemia. Visible cyanosis occurs when the desaturated hemoglobin concentration is >5 g/dl. Arterial hypoxemia stimulates increased red blood cell production, which increases oxygen carrying capacity. However, blood viscosity and resistance to flow also rise with the increase in PCV. Severe erythrocytosis (PCV >65%) can lead to microvascular sludging, poor tissue oxygenation, intravascular thrombosis, hemorrhage, stroke, and cardiac arrhythmias. Erythrocytosis can become extreme, with a PCV >80% in some animals. The possibility of a venous embolus crossing the shunt to the systemic circulation poses another danger in these cases.

Anomalies that most often cause cyanosis in dogs and cats are T of F and pulmonary arterial hypertension secondary to a large PDA, VSD, or ASD. Other complex but uncommon anomalies, such as transposition of the great vessels or truncus arteriosus, also send deoxygenated blood to the systemic circulation. Some collateral blood flow to the lungs develops from the bronchial arteries of the systemic circulation. These small tortuous vessels may increase the overall radiographic opacity of the central pulmonary fields.

Physical exertion tends to exacerbate right-to-left shunting and cyanosis because greater blood flow to skeletal muscle reduces total peripheral vascular resistance. Despite the pressure overload on the right heart, CHF is rare. The shunt provides an alternate pathway for high pressure flow.

# TETRALOGY OF FALLOT

# **Etiology and Pathophysiology**

The four components of the T of F are a VSD, PS, a dextropositioned aorta, and RV hypertrophy. The VSD can be quite large. The PS can involve the valve or infundibular area; in some cases, the pulmonary artery is hypoplastic or not open at all (atretic). The large aortic root extends over the right side of the interventricular septum and facilitates RV-toaortic shunting. Aortic anomalies exist in some animals as well. RV hypertrophy occurs in response to the pressure overload imposed by the PS and systemic arterial circulation. The volume of blood shunted from the RV into the aorta depends on the balance of outflow resistance caused by the fixed PS compared with systemic arterial resistance, which can vary. Exercise and other causes of decreased arterial resistance increase right-to-left shunt volume. Pulmonary vascular resistance is generally normal in animals with T of F. A polygenic inheritance pattern for T of F has been identified in the Keeshond. The defect also occurs in other dog breeds and in cats.

# **Clinical Features**

Exertional weakness, dyspnea, syncope, cyanosis, and stunted growth are common in the history. Physical examination findings are variable, depending on the relative severity of the malformations. Cyanosis is seen at rest in some animals. Others have pink mucous membranes, although cyanosis usually becomes evident with exercise in these cases. The precordial impulse is usually of equal intensity or stronger on the right chest wall than on the left. Inconsistently, a precordial thrill is palpable at the right sternal border or left basilar area. Jugular pulsation may be noted. A holosystolic murmur at the right sternal border consistent with a VSD, or a systolic ejection murmur at the left base compatible with PS, or both may be heard on auscultation. However, some animals have no audible murmur because hyperviscosity associated with polycythemia diminishes blood turbulence and therefore murmur intensity.

#### Diagnosis

Thoracic radiographs depict variable cardiomegaly, usually of the right heart (see Table 5-2). The main pulmonary artery may appear small, although a bulge is evident in some cases. Reduced pulmonary vascular markings are common, although a compensatory increase in bronchial circulation can increase the overall pulmonary opacity. The malpositioned aorta creates a cranial bulge in the heart shadow on lateral view. RV hypertrophy displaces the left heart dorsally and can simulate left heart enlargement. The ECG typically suggests RV enlargement, although a left axis deviation is seen in some affected cats.

Echocardiography depicts the VSD, a large aortic root shifted rightward and overriding the ventricular septum, some degree of PS, and RV hypertrophy. Doppler studies reveal the right-to-left shunt and high-velocity stenotic pulmonary outflow jet. An echo-contrast study also can

document the right-to-left shunt. Typical clinicopathologic abnormalities include increased PCV and arterial hypoxemia.

# **Treatment and Prognosis**

Definitive repair of T of F requires open-heart surgery. Palliative surgical procedures can increase pulmonary blood flow by creating a left-to-right shunt. Anastomosis of a subclavian artery to the pulmonary artery and the creation of a window between the ascending aorta and pulmonary artery are two techniques that have been used successfully.

Severe erythrocytosis and clinical signs associated with hyperviscosity (e.g., weakness, shortness of breath, seizures) can be treated with periodic phlebotomy (see p. 111) or alternatively, hydroxyurea (see p. 111). The goal is to maintain PCV at a level where clinical signs are minimal; further reduction of PCV (into the normal range) can exacerbate signs of hypoxia. A  $\beta$ -blocker may help reduce clinical signs in some dogs with T of F. Decreased sympathetic tone, RV contractility, RV (muscular) outflow obstruction, and myocardial oxygen consumption, along with increased peripheral vascular resistance, are potential benefits, although the exact mechanism is not clear. Exercise restriction is also advised. Drugs with systemic vasodilator effects should not be given.

The prognosis for animals with T of F depends on the severity of PS and erythrocytosis. Mildly affected animals and those that have had a successful palliative surgical shunting procedure may survive well into middle age. Nevertheless, progressive hypoxemia, erythrocytosis, and sudden death at an earlier age are common.

# PULMONARY HYPERTENSION WITH SHUNT REVERSAL

# **Etiology and Pathophysiology**

Pulmonary hypertension develops in a relatively small percentage of dogs and cats with shunts. The defects usually associated with development of pulmonary hypertension are PDA, VSD, AV septal defect or common AV canal, ASD, and aorticopulmonary window. The low-resistance pulmonary vascular system normally can accept a large increase in blood flow without marked increase in pulmonary arterial pressure. It is not clear why pulmonary hypertension develops in some animals, although the defect size in those animals is usually quite large. It is possible that the high fetal pulmonary resistance may not regress normally in these animals or their pulmonary vasculature may react abnormally to an initially large left-to-right shunt flow. In any case, irreversible histologic changes occur in the pulmonary arteries that increase vascular resistance. These include intimal thickening, medial hypertrophy, and characteristic plexiform lesions.

As pulmonary vascular resistance rises, pulmonary artery pressure increases and the volume of blood shunted from left-to-right diminishes. If the right heart and pulmonary pressures exceed those of the systemic circulation, the shunt reverses direction and deoxygenated blood flows into the

aorta. These changes appear to develop at an early age (e.g., by 6 months), although exceptions are possible. The term *Eisenmenger's physiology* refers to the severe pulmonary hypertension and shunt reversal that develop.

Right-to-left shunts that result from pulmonary hypertension cause pathophysiologic and clinical sequelae similar to those resulting from T of F. The major difference is that the impediment to pulmonary flow occurs at the level of the pulmonary arterioles rather than at the pulmonic valve. Hypoxemia, RV hypertrophy and enlargement, erythrocytosis and its consequences, increased shunting with exercise, and cyanosis can occur. Likewise, right-sided CHF is uncommon but can develop in response to secondary myocardial failure or tricuspid insufficiency. The right-to-left shunt permits venous emboli to cross into the arterial system, potentially resulting in stroke or other arterial embolization.

#### **Clinical Features**

The history and clinical presentation of animals with pulmonary hypertension and shunt reversal are similar to those associated with T of F. Exercise intolerance, shortness of breath, syncope (especially in association with exercise or excitement), seizures, and sudden death are common. Cough and hemoptysis may also occur. Cyanosis may be evident

only during exercise or excitement. Intracardiac shunts cause equally intense cyanosis throughout the body. Cyanosis of the caudal mucous membranes alone (differential cyanosis) is typically caused by a reversed PDA. Here, normally oxygenated blood flows to the cranial body by way of the brachycephalic trunk and left subclavian artery (from the aortic arch), and the rest of the body receives desaturated blood through the ductus, located in the descending aorta (Fig. 5-11). Rear limb weakness is common in animals with reversed PDA.

A murmur typical of the underlying defect(s) may be heard, but often no murmur or only a very soft systolic murmur is audible because blood viscosity is increased by polycythemia. There is no continuous murmur in patients with reversed PDA. Pulmonary hypertension often causes the S<sub>2</sub> sound to be loud and "snapping" or split. A gallop sound is occasionally heard. Other subtle physical examination findings include a pronounced right precordial impulse and jugular pulsations.

# Diagnosis

Thoracic radiographs typically reveal right heart enlargement; a prominent pulmonary trunk; and tortuous, proximally widened pulmonary arteries. A bulge in the descending

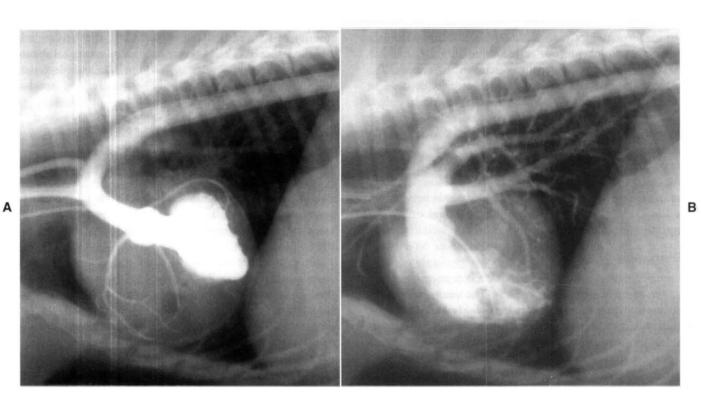

FIG 5-11

Angiocardiograms from an 8-month-old female Cocker Spaniel with patent ductus arteriosus, pulmonary hypertension, and shunt reversal. Left ventricular injection (A) shows dorsal displacement of the left ventricle by the enlarged right ventricle. Note the dilution of radiographic contrast solution in the descending aorta (from mixing with nonopacified blood from the ductus) and the prominent right coronary artery. Right ventricular injection (B) illustrates right ventricular hypertrophy and pulmonary trunk dilation secondary to severe pulmonary hypertension. Opacified blood courses through the large ductus into the descending aorta.

aorta may be seen in dogs with reversed PDA. The left heart in animals with a reversed PDA or VSD may be enlarged as well. The ECG usually suggests RV and sometimes RA enlargement, with a right axis deviation.

Echocardiography reveals the RV hypertrophy and intracardiac anatomic defects (and sometimes a large ductus), as well as pulmonary trunk dilation. Doppler or echo-contrast study can confirm an intracardiac right-to-left shunt. Reversed PDA flow can be shown by imaging the abdominal aorta during venous echocontrast injection. Peak RV (and in the absence of PS, pulmonary artery) pressure can be estimated by measuring the peak velocity of a tricuspid regurgitation jet. Pulmonary insufficiency flow can be used to estimate diastolic pulmonary artery pressure. Cardiac catheterization also can confirm the diagnosis and quantify the pulmonary hypertension and systemic hypoxemia.

# **Treatment and Prognosis**

Therapy is aimed at managing secondary erythrocytosis to minimize signs of hyperviscosity and attempting to reduce pulmonary arterial pressure, if possible. Exercise restriction is also advised. Erythrocytosis can be managed by periodic phlebotomy or use of oral hydroxyurea. It is unclear whether PCV alone should be used to guide treatment, although maintaining PCV at about 62% has previously been recommended. The ideal PCV for a patient would seem to be that associated with minimal physical manifestations of hyperviscosity (e.g., rear limb weakness, shortness of breath, lethargy). Surgical closure of the shunt is contraindicated. The prognosis is generally poor in animals with pulmonary hypertension and shunt reversal, but some patients have done well for years with medical management.

Phlebotomy can be done when necessary. One method is to remove 5 to 10 ml blood/kg body weight and administer an equal volume of isotonic fluid. Another technique (described by Cote and Ettinger, 2001) involves removing 10% of the patient's circulating blood volume initially without giving replacement fluid. This volume (ml) is calculated as  $8.5\% \times \text{body}$  weight (kg)  $\times 1000 \text{ g/kg} \times 1 \text{ ml/g}$ . After 3 to 6 hours of cage rest, an additional volume of blood is removed if the patient's initial PCV was >60%. This additional volume would be 5% to 10% of the circulating blood volume if initial PCV was 60% to 70%, or an additional 10% to 18% if initial PCV was >70%.

Hydroxyurea therapy (40 to 50 mg/kg by mouth q48h or 3×/week) can be a useful alternative to periodic phlebotomy in some patients with secondary erythrocytosis. A CBC and platelet count should be monitored weekly or biweekly to start. A PCV between approximately 55% to 60% is the suggested target. Possible adverse effects of hydroxyurea include anorexia, vomiting, bone marrow hypoplasia, alopecia, and pruritus. The dose can be divided q12h on treatment days, or administered twice weekly, or at <40 mg/kg depending on the patient's response.

Sildenafil citrate is a selective phosphodiesterase-5 inhibitor that may reduce pulmonary resistance via nitric oxide—dependent pulmonary vasodilation. It appears to improve

clinical signs and exercise tolerance in some dogs with pulmonary hypertension, although experience in animals is limited. Doses of 0.5 to 2(or 3) mg/kg q12h or q8h seem to be well-tolerated and produce some reduction in Doppler-cstimated pulmonary artery pressure. Lower initial doses are suggested, with gradual up-titration. Adverse effects of sildenafil can include possible nasal congestion, hypotension, or sexual adverse effects, especially in intact animals. Other vasodilator drugs tend to produce systemic effects that are similar to or greater than those on the pulmonary vasculature; therefore they are of little benefit and possibly detrimental. Low-dose aspirin (e.g., 5 mg/kg) therapy may also be useful in animals with pulmonary hypertension and reversed shunt, but this is not well-studied.

# OTHER CARDIOVASCULAR ANOMALIES

# **VASCULAR RING ANOMALIES**

Various vascular malformations originating from the embryonic aortic arch system can occur. These can entrap the esophagus and sometimes the trachea within a vascular ring at the dorsal heart base. Persistent right aortic arch is the most common vascular ring anomaly in the dog. This developmental malformation surrounds the esophagus: dorsally and to the right with the aortic arch, to the left with the ligamentum arteriosum, and ventrally with the base of the heart. Different vascular ring anomalies can occur as well. In addition, other vascular malformations, such as a left cranial vena cava or PDA, may accompany a vascular ring anomaly. Vascular ring anomalies are rare in cats.

The vascular ring prevents solid food from passing normally through the esophagus. Clinical signs of regurgitation and stunted growth commonly develop within 6 months of weaning. Esophageal dilation occurs cranial to the ring; food may be retained in this area. Sometimes the esophagus dilates caudal to the stricture as well, indicating that altered esophageal motility coexists. Respiratory signs including coughing, wheezing, and cyanosis usually signal secondary aspiration pneumonia. However, in some cases a double aortic arch can cause stridor and other respiratory signs secondary to tracheal stenosis.

The animal's body condition score may be normal initially, but progressive debilitation ensues. A palpably dilated cervical esophagus (containing food or gas) is evident at the thoracic inlet in some cases. Fever and respiratory signs suggest aspiration pneumonia. Vascular ring anomalies by themselves do not result in abnormal cardiac sounds.

Thoracic radiographs show a leftward tracheal deviation near the cranial heart border on DV view. Other common signs include a widened cranial mediastinum, focal narrowing and/or ventral displacement of the trachea, air or food in the cranial thoracic esophagus, and sometimes evidence of aspiration pneumonia. A barium swallow allows visualization of the esophageal stricture over the heartbase and cranial esophageal dilation (with or without caudal esophageal dilation).

Surgical division of the ligamentum arteriosum, or other vessel if the anomaly is not a persistent right aortic arch, is the recommended therapy. In some cases a retroesophageal left subclavian artery or left aortic arch is also present and must be divided to free the esophagus. Medical management consists of frequent small, semisolid, or liquid meals eaten in an upright position. This feeding method may be necessary indefinitely. Persistent regurgitation occurs in some dogs despite successful surgery, suggesting a permanent esophageal motility disorder.

# COR TRIATRIATUM

Cor triatriatum is an uncommon malformation caused by an abnormal membrane that divides either the right (dexter) or the left (sinister) atrium into two chambers. Cor triatriatum dexter occurs sporadically in dogs; cor triatriatum sinister has been described only rarely. Cor triatriatum dexter results from failure of the embryonic right sinus venosus valve to regress. The caudal vena cava and coronary sinus empty into the RA caudal to the intra-atrial membrane; the tricuspid orifice is within the cranial RA "chamber." Obstruction to venous flow through the opening in the abnormal membrane elevates vascular pressure in the caudal vena cava and the structures that drain into it.

Large- to medium-size breeds of dog are most often affected. Persistent ascites that develops at an early age is the most prominent clinical sign. Exercise intolerance, lethargy, distended cutaneous abdominal veins, and sometimes diarrhea are reported also. Neither a cardiac murmur nor jugular venous distention are features of this anomaly.

Thoracic radiographs indicate caudal vena caval distention without generalized cardiomegaly. The diaphragm may be displaced cranially by massive ascites. The ECG is usually normal. Echocardiography reveals the abnormal membrane and prominence of the caudal RA chamber and vena cava. Doppler studies show the flow disturbance within the RA and allow the intra-RA pressure gradient to be estimated.

Successful therapy requires enlarging the membrane orifice or excising the abnormal membrane to remove flow obstruction. A surgical approach using inflow occlusion, with or without hypothermia, can be used to excise the membrane or break it down using a valve dilator. A much less invasive option is percutaneous balloon dilation of the membrane orifice. This works well as long as a sufficiently large balloon is used. Several balloon dilation catheters placed simultaneously may be needed for effective dilation in larger dogs.

#### **ENDOCARDIAL FIBROELASTOSIS**

Diffuse fibrosis and elastic thickening of the endocardium characterize the congenital abnormality endocardial fibroelastosis. It is reported more commonly in cats, especially Burmese and Siamese, but has been observed rarely in dogs. Left-sided or biventricular heart failure commonly develops early in life. A mitral regurgitation murmur may be present. Criteria for LV and LA enlargement are seen on radiographs, ECG, and echocardiogram. Evidence for reduced LV myo-

cardial systolic and diastolic function may be present. Definitive antemortem diagnosis is difficult.

#### **OTHER VASCULAR ANOMALIES**

A number of venous anomalies have been described. Many are not clinically important. The persistent left cranial vena cava is a fetal venous remnant that courses lateral to the left AV groove and empties into the coronary sinus of the caudal RA. Although it causes no clinical signs, its presence may complicate surgical exposure of other structures at the left heartbase. Portosystemic venous shunts are common and can lead to hepatic encephalopathy as well as other signs. These malformations are thought to be more prevalent in the Yorkshire Terrier, Pug, Miniature and Standard Schnauzers, Maltese, Pekingese, Shih Tzu, and Lhasa Apso breeds.

# CHAPTER OUTLINE

DEGENERATIVE ATRIOVENTRICULAR VALVE DISEASE Radiography Electrocardiography Echocardiography INFECTIVE ENDOCARDITIS

# DEGENERATIVE ATRIOVENTRICULAR VALVE DISEASE

Chronic degenerative atrioventricular (AV) valve disease is the most common cause of heart failure in the dog. This condition is also known as endocardiosis, mucoid or myxomatous valvular degeneration, or chronic valvular fibrosis. Because clinically relevant degenerative valve disease is rare in cats, this chapter will focus on canine chronic valvular disease. The mitral valve is affected most often and to a greater degree, but degenerative lesions also involve the tricuspid valve in many dogs. However, isolated degenerative disease of the tricuspid valve is uncommon. Thickening of the aortic and pulmonic valves sometimes is observed in older animals but rarely causes more than mild insufficiency.

#### **Etiology and Pathophysiology**

The cause of degenerative AV valve disease is unclear, but a hereditary basis is likely. Middle-aged and older small to mid-size breeds are most often affected. Disease prevalence and severity increase with age. About a third of small-breed dogs older than 10 years of age are affected. Commonly affected breeds include Toy and Miniature Poodles, Miniature Schnauzers, Chihuahuas, Pomeranians, Fox Terriers, Cocker Spaniels, Pekingese, Boston Terriers, Miniature Pinschers, Whippets, and Cavalier King Charles Spaniels. An especially high prevalence and an early onset of degenerative mitral valve disease (MVD) is reported in Cavalier King Charles Spaniels, in which inheritance is thought to be poly-

genic, with gender and age influencing expression. It appears that the overall prevalence of mitral regurgitation (MR) murmurs and degenerative valve disease is similar in male and female dogs, but males may have faster disease progression. Some large-breed dogs are affected also, and the prevalence may be higher in German Shepherd Dogs.

Multiple factors involving collagen degeneration, valve leaflet stress, and endothelial function are thought to be involved. Pathologic valve changes develop gradually with age. Early lesions consist of small nodules on the free margins of the valve; these become larger, coalescing plaques that thicken and distort the valve. The histologic changes have been described as *myxomatous degeneration*. Collagen within the affected leaflets degenerates, and acid mucopolysaccharides and other substances accumulate within the layers of the leaflets, resulting in nodular thickening, deformity, and weakening of the valve as well as its chordae tendineae. Redundant tissue between chordal attachments often bulges (prolapses) like a parachute or balloon toward the atrium. Mitral valve prolapse may be important in the pathogenesis of the disease, at least in some breeds.

Affected valves gradually begin to leak because their edges do not coapt properly. As the lesions progress, the valve insufficiency (regurgitation) becomes clinically evident. Atrial jet lesions; endocardial fibrosis; and, in patients with advanced disease, partial or even full-thickness atrial tears can form. Chronic valvular disease is also associated with intramural coronary arteriosclerosis, microscopic intramural myocardial infarctions, and focal myocardial fibrosis. The extent to which these changes cause clinical myocardial dysfunction is not clear; however, impaired myocardial contractility is observed late in the disease. Interestingly, senior dogs without valvular disease also have similar vascular lesions.

The pathophysiologic changes relate to volume overload on the affected side of the heart after the valve or valves become incompetent. Regurgitation usually develops slowly over months to years. Mean atrial pressure usually remains fairly low during this time, unless a sudden increase in regurgitant volume (e.g., ruptured chordae) occurs. With advancing valve degeneration, a progressively larger volume of blood moves ineffectually back and forth between the ven-

tricle and atrium, diminishing the forward flow to the aorta. Compensatory mechanisms augment blood volume to meet the circulatory needs of the body (see Chapter 3), including increased sympathetic activity, attenuated vagal tone, and renin-angiotensin-aldosterone system (RAAS) activation. Natriuretic peptide release occurs; higher atrial natriuretic peptide concentrations have been associated with marked left atrium (LA) enlargement and severe congestive heart failure (CHF). The affected ventricle and atrium dilate to accept the growing regurgitant volume and the required forward stroke volume; eccentric myocardial hypertrophy develops in an attempt to normalize the resulting increase in wall stress.

These compensatory changes in heart size and blood volume allow most dogs to remain asymptomatic for a prolonged period. Massive LA enlargement may develop before any signs of heart failure appear, and some dogs never show clinical signs of heart failure. The rate at which the regurgitation worsens, as well as the degree of atrial distensibility and ventricular contractility, influence how well the disease is tolerated. A gradual increase in atrial, pulmonary venous, and capillary hydrostatic pressures stimulates compensatory increases in pulmonary lymphatic flow. Overt pulmonary edema develops when the capacity of the pulmonary lymphatic system is exceeded. Tricuspid insufficiency may be severe enough to cause right-sided CHF. Increased pulmonary vascular pressure secondary to chronic left-sided CHF may also contribute to the development of right-sided heart failure.

Ventricular pump function is maintained fairly well until late in the disease in many dogs, even in the face of severe congestive signs. Nevertheless, chronic volume overload eventually reduces myocyte contractility. The mechanism of myocardial dysfunction may involve damage from oxygen free radicals as well as neurohormonal activation. Reduced contractility exacerbates ventricular dilation and valve regurgitation and therefore can worsen CHF. Assessment of left ventricular (LV) contractility in animals with MR is complicated by the fact that the most commonly used clinical indices (e.g., echocardiographic fractional shortening, ejection fraction) overestimate contractility because they are obtained during ejection and are therefore affected by the reduced ventricular afterload caused by MR. The echocardiographic estimation of the end-systolic volume index may be useful (see p. 41). This index suggests that myocardial function is normal to mildly depressed in most dogs with chronic mitral degeneration. A number of other echo/ Doppler indices can also help assess LV systolic and diastolic function.

# **Complicating Factors**

Although this disease usually progresses slowly, certain complicating events can precipitate acute clinical signs in dogs with previously compensated disease (Box 6-1). For example, tachyarrhythmias may be severe enough to cause decompensated CHF, syncope, or both. Frequent atrial premature contractions, paroxysmal atrial tachycardia, or atrial fibrilla-

tion can reduce ventricular filling time and cardiac output, increase myocardial oxygen needs, and worsen pulmonary congestion and edema. Ventricular tachyarrhythmias also occur but are less common.

Sudden rupture of diseased chordae tendineae acutely increases regurgitant volume and can precipitate fulminant pulmonary edema within hours in previously compensated or even asymptomatic dogs. Signs of low cardiac output may also occur. Sometimes, ruptured chordae tendineae are an incidental finding (on an echocardiogram or at necropsy), especially if second- or third-order chordae are involved.

Massive LA enlargement itself can result in compression of the left mainstem bronchus and stimulate persistent coughing, even in the absence of CHF. Furthermore, massive left (or right) atrial distention can result in partial- or fullthickness tearing. Atrial wall rupture usually causes acute cardiac tamponade; there appears to be a higher prevalence

BOX 6-1

Potential Complications of Chronic Atrioventricular Valve Disease

#### **Causes of Acutely Worsened Pulmonary Edema**

Arrhythmias

Frequent atrial premature complexes

Paroxysmal atrial/supraventricular tachycardia

Atrial fibrillation

Frequent ventricular tachyarrhythmias

Rule out drug toxicity (e.g., digoxin)

Ruptured chordae tendineae

latrogenic volume overload

Excessive volumes of IV fluids or blood

High-sodium fluids

Erratic or improper medication administration

Insufficient medication for stage of disease

Increased cardiac workload

Physical exertion

Anemia

Infections/sepsis

Hypertension

Disease of other organ systems (e.g., pulmonary, renal,

liver, endocrine)

Hot, humid environment

Excessively cold environment

Other environmental stresses

High salt intake

Myocardial degeneration and poor contractility

#### Causes of Reduced Cardiac Output or Weakness

Arrhythmias (see above)

Ruptured chordae tendineae

Cough-syncope

Left atrial tear

Intrapericardial bleeding

Cardiac tamponade

Increased cardiac workload (see above)

Secondary right-sided heart failure

Myocardial degeneration and poor contractility

of this complication in male Miniature Poodles, Cocker Spaniels, and Dachshunds. In most of these cases, severe valve disease; marked atrial enlargement; atrial jet lesions; and, often, ruptured first-order chordae tendineae are present.

#### **Clinical Features**

Degenerative AV valve disease may cause no clinical signs for years, and some dogs never develop signs of heart failure. In those that do, the signs usually relate to decreased exercise tolerance and manifestations of pulmonary congestion and edema. Diminished exercise capacity and cough or tachypnea with exertion are common initial owner complaints. As pulmonary congestion and interstitial edema worsen, the resting respiratory rate increases. Coughing tends to occur at night and early morning, as well as in association with activity. Severe edema results in obvious respiratory distress and usually a moist cough. Signs of severe pulmonary edema can develop gradually or acutely. Intermittent episodes of symptomatic pulmonary edema interspersed with periods of compensated heart failure occurring over months to years are also common. Episodes of transient weakness or acute collapse (syncope) can occur secondary to arrhythmias, coughing, or an atrial tear. Signs of tricuspid regurgitation (TR) are often overshadowed by those of MR but include ascites; respiratory distress from pleural effusion; and, rarely, subcutaneous edema. Splanchnic congestion may precipitate gastrointestinal signs. The cough caused by main bronchus compression often is described as "honking."

A holosystolic murmur heard best in the area of the left apex (left fourth to sixth intercostal space) is typical in patients with MR. The murmur can radiate in any direction. Mild regurgitation may be inaudible or cause a murmur only in early systole (protosystolic). Exercise and excitement often increase the intensity of soft MR murmurs. Louder murmurs have been associated with more advanced disease, but in dogs with massive regurgitation and severe heart failure, the murmur can be soft or even inaudible. Occasionally, the murmur sounds like a musical tone or whoop. Some dogs with chronic mitral disease have a mid- to late-systolic click, with or without a murmur. An S<sub>3</sub> gallop may be audible at the left apex in dogs with advanced disease. TR typically causes a holosystolic murmur best heard at the right apex. Features that aid in differentiating a TR murmur from radiation of an MR murmur to the right chest wall include jugular vein pulsations, a precordial thrill over the right apex, and a different quality to the murmur heard over the tricuspid region.

Pulmonary sounds can be normal or abnormal. Accentuated, harsh breath sounds and end-inspiratory crackles (especially in ventral lung fields) develop as pulmonary edema worsens. Fulminant pulmonary edema causes widespread inspiratory as well as expiratory crackles and wheezes. Some dogs with chronic MR have abnormal lung sounds caused by underlying pulmonary or airway disease rather than CHF. Dogs with CHF tend to have sinus tachycardia; those with chronic pulmonary disease frequently have

marked sinus arrhythmia and a normal heart rate. Pleural effusion causes diminished pulmonary sounds ventrally.

Other physical examination findings may be normal or noncontributory. Peripheral capillary perfusion and arterial pulse strength are usually good, although pulse deficits may be present in dogs with tachyarrhythmias. A palpable precordial thrill accompanies loud (grade 5-6/6) murmurs. Jugular vein distention and pulsations are not expected in dogs with MR alone. In animals with TR, jugular pulses occur during ventricular systole; these are more evident after exercise or in association with excitement. Jugular venous distention results from elevated right heart filling pressures. Jugular pulsations and distention are more evident with cranial abdominal compression (positive hepatojugular reflux). Ascites or hepatomegaly may be evident in dogs with right-sided CHF.

# Diagnosis

#### RADIOGRAPHY

Thoracic radiographs typically show some degree of LA and LV enlargement (see p. 13), which progresses over months to years (Fig. 6-1). As LA size increases, dorsal main bronchus displacement occurs. Severe LA enlargement causes compression of the left mainstem bronchus. Fluoroscopy may demonstrate dynamic main bronchus collapse during coughing or even quiet breathing in such animals. Extreme dilation of the LA can result over time, even without clinical heart failure. Variable right heart enlargement occurs with chronic TR, but this may be masked by left heart and pulmonary changes associated with concurrent MVD.

Pulmonary venous congestion and interstitial edema occur with the onset of left-sided CHF; progressive interstitial and alveolar pulmonary edema may follow. Although cardiogenic pulmonary edema in dogs typically has a hilar, dorsocaudal, and bilaterally symmetric pattern, an asymmetric distribution is seen in some dogs. The presence and severity of pulmonary edema do not necessarily correlate with the degree of cardiomegaly. Acute, severe MR (e.g., with rupture of the chordae tendineae) can cause severe edema in the presence of minimal LA enlargement. Conversely, slowly worsening MR can produce massive LA enlargement with no evidence of CHF. Early signs of right-sided heart failure include caudal vena caval distention, pleural fissure lines, and hepatomegaly. Overt pleural effusion and ascites occur with advanced failure.

#### ELECTROCARDOGRAPHY

The electrocardiogram (ECG) may suggest LA or biatrial enlargement and LV dilation (see p. 28), although the tracing is often normal. An RV enlargement pattern is occasionally seen in dogs with severe TR. Arrhythmias, especially sinus tachycardia, supraventricular premature complexes, paroxysmal or sustained supraventricular tachycardias, ventricular premature complexes, and atrial fibrillation are common in dogs with advanced disease. These arrhythmias may be associated with decompensated CHF, weakness, or syncope.

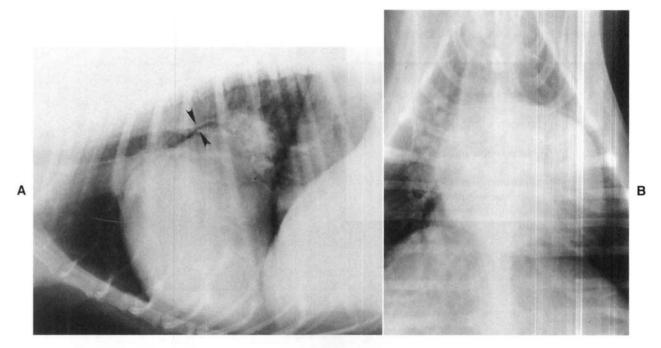

FIG 6-1
Lateral (A) and dorsoventral (B) radiographs from a Poodle with advanced mitral valve insufficiency. Note marked left ventricular and atrial enlargement and narrowing of left mainstem bronchus (arrowheads in A).

#### **ECHOCARDIOGRAPHY**

Echocardiography shows the atrial and ventricular chamber dilation secondary to chronic AV valve insufficiency. Depending on the degree of volume overload, this enlargement can be severe. Vigorous LV wall and septal motion are seen with MR when contractility is normal (Fig. 6-2); fractional shortening is high, and there is little to no E point-septal separation. Although ventricular diastolic dimension is increased, systolic dimension is normal until myocardial failure ensues. Calculation of end-systolic volume index may help in assessing myocardial function. Ventricular wall thickness is typically normal in dogs with chronic AV valve disease. With severe TR, paradoxical septal motion may occur along with the right ventricular (RV) and right atrial (RA) dilation. Pericardial fluid (blood) is seen after an LA tear, and evidence for cardiac tamponade may be evident. Mild pericardial effusion may also accompany signs of right-sided CHF.

Affected valve cusps are thickened and may appear knobby. Smooth thickening is characteristic of degenerative disease (endocardiosis). Conversely, rough and irregular vegetative valve lesions are characteristic of bacterial endocarditis; however, clear differentiation between these by echocardiography alone may be impossible. Systolic prolapse involving one or both valve leaflets is common with degenerative AV valve disease (Fig. 6-3, A). A ruptured chorda tendinea or leaflet tip sometimes is seen flailing into the atrium during systole (Figure 6-3, B). The direction and extent of flow disturbance can be seen with color-flow Doppler (see Figure 2-35). Although the size of the disturbed

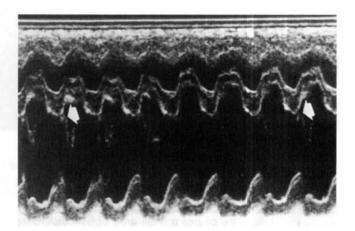

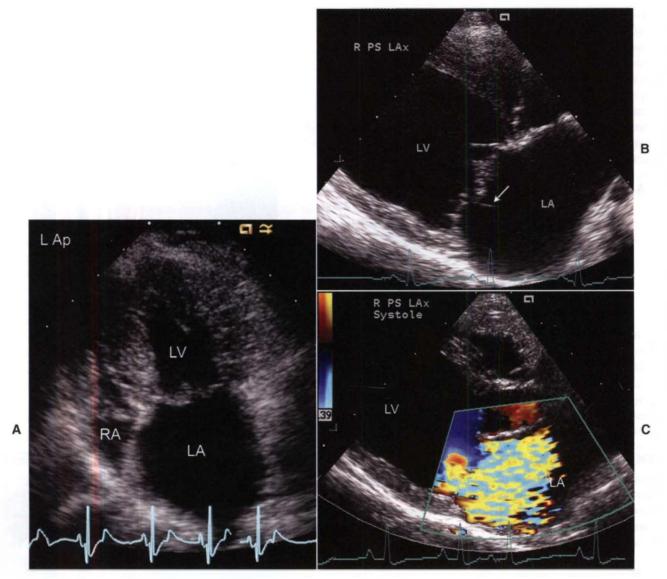

FIG 6-2
Sample M-mode echocardiogram from male Maltese with advanced mitral valve insufficiency and left-sided heart failure. Note accentuated septal and left ventricular posterior wall motion (fractional shortening = 50%) and lack of mitral valve E point-septal separation (arrows).

flow area provides a rough estimate of regurgitation severity, there are technical limitations with this. The proximal isovelocity surface area (PISA) method is considered by some to be a more accurate way to estimate MR severity. Other Doppler techniques can be used to evaluate systolic and diastolic ventricular function. Maximal TR jet velocity indicates whether pulmonary hypertension is present and its severity.

**FIG 6-3 A,** Thick, mildly prolapsing mitral valve and LA enlargement are seen from the left apical position in an older Dachshund with severe degenerative AV valve disease. The tricuspid valve is also thick. **B,** Chorda tendineae rupture is evident by the flail segment (arrow) seen in the enlarged LA of an older mixed breed dog. **C,** A large jet of mitral regurgitation causes a wide area of flow disturbance in another mixed breed dog on color flow echo. Note the LA and LV enlargement. LA, Left atrium; LV, left ventricle; RA, right atrium.

# **Clinicopathologic Findings**

Clinical laboratory data may be normal or reflect changes associated with CHF or concurrent extracardiac disease. Other diseases produce signs similar to those of CHF resulting from degenerative AV valve disease, including tracheal collapse, chronic bronchitis, bronchiectasis, pulmonary fibrosis, pulmonary neoplasia, pneumonia, pharyngitis, heartworm disease, dilated cardiomyopathy, and bacterial endocarditis.

# **Treatment and Prognosis**

Medical therapy is used to control signs of CHF as well as support cardiac function and modulate the excessive neurohormonal activation that contributes to the disease process (Box 6-2). Drugs that decrease LV size (e.g., diuretics, vaso-dilators, positive inotropic agents) may reduce the regurgitant volume by decreasing mitral annulus size. Drugs that promote arteriolar vasodilation enhance forward cardiac output and reduce regurgitant volume by decreasing systemic arteriolar resistance. Frequent reevaluation and medication adjustment become necessary as the disease progresses. In many dogs with advanced MR, clinical compensation can be maintained for months to years using appropriate therapy. Although congestive signs develop gradually in some dogs, severe pulmonary edema or episodes of syncope appear acutely in others. Intermittent episodes of decompensation

#### Treatment Guidelines for Chronic Atrioventricular Valve Disease

# Asymptomatic (Modified AHA/ACC Stage B)

Client education (about disease process and early heart failure signs)

Routine health maintenance

Blood pressure measurement

Baseline chest radiographs (+/- echocardiogram) and yearly rechecks

Maintain normal body weight/condition

Regular mild to moderate exercise

Avoid excessively strenuous activity

Heartworm testing and prophylaxis in endemic areas

Manage other medical problems

Avoid high-salt foods; consider moderately salt-restricted

Consider ACE inhibitor if marked increase in LA +/- LV enlargement occurs; additional therapies aimed against neurohormonal activation may or may not be clinically useful

## Mild to Moderate CHF signs (Modified AHA/ACC Stage C, Chronic)\*

Considerations as above, and

Furosemide, as needed

ACE inhibitor (or pimobendan)

Pimobendan (can use with or without ACE inhibitor)

+/- Digoxin (indicated with atrial tachyarrhythmias, including fibrillation)

+/- Additional diuretic (spironolactone, hydrochlorothiazide) Antiarrhythmic therapy if necessary

Complete exercise restriction until signs abate

Moderate dietary salt restriction

Resting respiratory (+/- heart) rate monitoring at home

# Severe, Acute CHF Signs (Modified AHA/ACC Stage C, Acute)\*

Supplemental O<sub>2</sub>

Cage rest and minimal patient handling

Furosemide (more aggressive doses, parenteral)

Vasodilator therapy

Consider IV nitroprusside, or

Oral hydralazine or amlodipine, +/- topical nitroglycerine

+/- Butorphanol or morphine

Antiarrhythmic therapy, if necessary

+/- Positive inotropic drug:

If myocardial failure documented, IV drug can be used (see Box 3-1).

After patient stabilized, can use long-term oral pimobendan +/- digoxin therapy

+/- Bronchodilator

Thoracocentesis, if large volume pleural effusion

### **Chronic Recurrent or Refractory Heart Failure Strategies** (Modified AHA/ACC Stage D)\*

Ensure that therapies for stage C are being given at optimal doses and intervals, including furosemide, ACE inhibitor, pimobendan and/or digoxin, spironolactone

Rule out systemic arterial hypertension, arrhythmias, anemia, and other complications

Increase furosemide dose/frequency; may be able to decrease again in several days after signs abate

Enforced rest until signs abate

Add pimobendan, if not currently prescribed

Increase ACE inhibitor dose/frequency (to g12h from q24h)

Add digoxin, if not currently prescribed; monitor serum concentration; increase dose only if subtherapeutic concentration documented

Add (or increase dose of) second diuretic (e.g., spironolactone, hydrochlorothiazide)

Additional afterload reduction (e.g., amlodipine or hydralazine); monitor blood pressure

Further restrict dietary salt intake; verify that drinking water is low in sodium

Thoracocentesis (or abdomincentesis) as needed Manage arrhythmias, if present (see Chapter 4)

Consider sildenafil for secondary pulmonary hypertension

(e.g., 1-2 mg/kg q8-12h)

Consider bronchodilator trial, or cough suppressant

in dogs on long-term CHF therapy often can be successfully managed. Therapy must be guided by the patient's clinical status and the nature of complicating factors. Surgical procedures such as mitral annuloplasty, other valve repair techniques, and mitral valve replacement may be treatment options in some patients but are not widely available.

# **Asymptomatic Atrioventricular Valve Regurgitation**

Dogs that have shown no clinical signs of disease are generally not given drug therapy. Convincing evidence that angiotensin-converting enzyme inhibitor (ACEI) or other therapy delays time to CHF onset in asymptomatic dogs is presently lacking. Whether dogs with marked cardiomegaly might benefit from therapy to modulate pathologic remodeling is unclear.

Client education about the disease process and early signs of CHF is important. It is probably prudent to discourage high-salt foods, pursue weight reduction for obese dogs, and avoid prolonged strenuous exercise. A diet moderately reduced in salt may be helpful. Periodic reevaluation (e.g., every 6 to 12 months) of cardiac size and function as well as blood pressure is advised. Other disease conditions are managed as appropriate.

<sup>\*</sup> See Tables 3-2, 3-3, and Box 3-1 for further details and doses.

# Mild to Moderate Congestive Heart Failure

When clinical signs occur in association with exercise or activity, several treatment modalities are instituted (see Box 6-2 and Tables 3-3 and Box 3-1). The severity of clinical signs and the nature of any complicating factors influence the aggressiveness of therapy. When it is unclear whether respiratory signs are caused by early CHF or a noncardiac cause, a therapeutic trial of furosemide (e.g., 1 to 2 mg/kg by mouth q8-12h) is indicated. Cardiogenic pulmonary edema usually responds rapidly.

Furosemide is used for dogs with radiographic evidence of pulmonary edema and/or more severe clinical signs. Higher and more frequent doses are used when edema is severe. After signs of failure are controlled, the dose and frequency of furosemide administration are gradually reduced to the lowest effective levels for chronic therapy. Furosemide alone (e.g., without an ACEI or other agent) is not recommended for the long-term treatment of heart failure.

An ACEI is generally recommended for dogs with early signs of failure (see Chapter 3). The ability of these agents to modulate neurohormonal responses to heart failure is thought to be their main advantage. Chronic ACEI therapy can improve exercise tolerance, cough, and respiratory effort, although the issue of enhanced survival is unclear.

Pimobendan also is being used increasingly for the management of moderate to advanced CHF (see Chapter 3). This drug has positive inotropic, vasodilator, and other actions. Its beneficial effects may exceed those of ACEIs, although they are often used together. Digoxin, with or without pimobendan, is often added to the chronic therapy of CHF resulting from advanced AV valve insufficiency. Digoxin's sensitizing effect on baroreceptors may be more advantageous than its modest positive inotropic effect (see Chapter 3). Marked LV dilation, evidence for reduced myocardial contractility, or recurrent episodes of pulmonary edema despite furosemide and other treatment are indications for adding digoxin. Digoxin also is indicated for heart rate control in dogs with atrial fibrillation and for its antiarrhythmic effect in some cases of frequent atrial premature beats or supraventricular tachycardia. Conservative doses and measurement of serum concentrations are recommended to prevent toxicity (see p. 66).

Moderate dietary salt restriction (e.g., diets formulated for dogs with kidney disease or for senior dogs) is recommended initially. Further salt restriction may be achieved with diets formulated for patients with heart failure. Exercise restriction is important when signs of CHF exist. Mild to moderate, regular activity (not causing undue respiratory effort) may be resumed during chronic, compensated disease. Strenuous exercise is not recommended. Antitussive therapy can be helpful in dogs without pulmonary edema but with persistent cough caused by mechanical mainstem bronchus compression (e.g., hydrocodone bitartrate, 0.25 mg/kg by mouth q8-12h; or butorphanol, 0.5 mg/kg by mouth q6-12h).

# Severe Congestive Heart Failure

Severe pulmonary edema and shortness of breath at rest require urgent treatment (see Box 3-1). Aggressive diuresis with parenteral furosemide (e.g., 2 to 4 mg/kg q1-4h IV, initially), supplemental oxygen, and cage rest are instituted as soon as possible. Gentle handling is important because added stress may precipitate cardiopulmonary arrest. Thoracic radiographs and other diagnostic procedures are postponed until the animal's respiratory condition is more stable.

Vasodilator therapy is also indicated. If adequate monitoring facilities are available, intravenous (IV) nitroprusside may be used for rapid arteriolar and venous dilation; however, blood pressure must be closely monitored to prevent hypotension. Another approach for acute therapy is oral hydralazine. Its direct and rapid arteriolar vasodilating effect increases forward flow and decreases regurgitation; however, oral administration can be stressful. A reduced dose is used in animals already on an ACEI. Amlodipine is an alternative arteriolar vasodilator, but it has a much slower onset of action. Topical nitroglycerin also can be used in an attempt to reduce pulmonary venous pressure by direct venodilation.

When positive inotropic therapy is indicated, pimobendan (or digoxin) may be initiated (or continued if previously prescribed) once acute dyspnea subsides. Paroxysmal atrial tachycardia or atrial fibrillation may respond to digoxin. Although several days are needed to achieve a therapeutic blood concentration with oral maintenance doses, IV digitalization is generally not recommended. Diltiazem or a  $\beta$ -blocker (see Table 4-2) can be used instead of or in addition to digoxin if supraventricular tachyarrhythmias require treatment (see Chapter 4). Dogs that need more intense inotropic support or that have persistent hypotension can be given an IV agent (e.g., dobutamine, dopamine, amrinone; see Box 3-1).

Ancillary therapy often includes mild sedation to reduce anxiety (e.g., butorphanol or morphine). A bronchodilator (e.g., theophylline, aminophylline) may be useful if bronchospasm is induced by severe pulmonary edema; although efficacy for this is unclear, these agents may help support respiratory muscle function.

Thoracocentesis is indicated in dogs with moderate- to large-volume pleural effusion to improve pulmonary function. Ascites that impedes respiration also should be drained. Therapy for ventricular tachyarrhythmias is warranted in some cases. Close monitoring is important for titrating therapy and identifying drug toxicities or adverse effects (e.g., azotemia, electrolyte abnormalities, hypotension, arrhythmias).

After the animal's condition is stabilized, medications are adjusted over several days to weeks to determine optimal long-term therapy. Furosemide is titrated to the lowest dose (and longest interval) that controls signs of CHF. Institution of an ACEI is recommended for ongoing therapy if hydralazine or nitroprusside was the initial vasodilator used. As the effects of previously administered hydralazine wane, the first dose of ACEI given should be half the usual dose

(i.e., 0.25 mg/kg by mouth). An ACEI can be started at the standard dose shortly after discontinuing a nitroprusside infusion.

# **Chronic Management of Advanced Disease**

When CHF becomes refractory, therapy is intensified or modified according to individual patient needs. The following suggestions for modifying therapy are listed in approximate order of use. Recurrent pulmonary edema in some dogs responds to an increased dose of furosemide and rest for a few days. The dose can then be returned to previous or a slightly higher level, if possible. The ACEI dose should be maximized if this has not already been done (e.g., enalapril from once to twice daily).

Pimobendan and/or digoxin can be added if it is not already being used. The dose of digoxin is not titrated upward unless subtherapeutic serum concentrations are documented (see Chapter 3). Spironolactone can be added, if not already being used (see Chapter 3). This aldosterone antagonist may reduce the severity of chronic refractory pulmonary edema or effusions as well as have beneficial effects on cardiac remodeling. Conversely, another diuretic with a different mechanism of action or the spironolactone/hydrochlorothiazide combination product may be useful.

Continued monitoring, especially of renal function and serum electrolyte concentrations, is important. Dietary sodium restriction can be intensified. If the ACEI and furosemide doses are already maximal, low-dose hydralazine (e. g., 0.25 to 0.5 mg/kg by mouth q12h) or amlodipine (e.g., 0.05 to 0.2 mg/kg by mouth q24h) can be added, although blood pressure should be monitored.

Intermittent tachyarrhythmias can promote decompensated CHF as well as episodes of transient weakness or syncope. Cough-induced syncope, atrial rupture, or other causes of reduced cardiac output may also occur. Despite the periodic recurrence of signs of CHF, many dogs with chronic AV valve regurgitation can enjoy a good quality of life for several years after the signs of failure first appear.

# **Patient Monitoring and Reevaluation**

Client education regarding the disease process, the clinical signs of failure, and the drugs used to control them is essential for long-term therapy to be successful. As the disease progresses, medication readjustment (i.e., different dosages of currently used drugs and/or additional drugs) is expected. Several common potential complications of chronic degenerative AV valve disease can cause decompensation (see Box 6-1). At-home monitoring is important to detect early signs of decompensation. Respiratory (+/- heart) rate can be monitored periodically when the dog is quietly resting or sleeping (see p. 70; a persistent increase in either can signal early decompensation.

Asymptomatic dogs should be reevaluated at least yearly in the context of a routine preventive health program. The frequency of reevaluation in dogs receiving medication for heart failure depends on the disease severity and whether any complicating factors are present. Dogs with recently diag-

nosed or decompensated CHF should be evaluated more frequently (within several days to a week or so) until their condition is stable. Those with chronic heart failure that appears well-controlled can be reevaluated less frequently, usually several times per year. The medication supply, administration compliance, drugs and doses being given, and diet should be reviewed with the owner at each visit.

A general physical exam with particular attention to cardiovascular parameters is important at each visit. An ECG is indicated if an arrhythmia or unexpectedly low or high heart rate is found. When an arrhythmia is suspected but not documented on routine ECG, ambulatory electrocardiography (e.g., 24-hour Holter monitoring) can be helpful. The respiratory rate and pattern are also noted; thoracic radiographs are warranted if abnormal pulmonary sounds are heard or if the owner reports coughing, other respiratory signs, or an increased resting respiratory rate. Other causes of cough should be considered if neither pulmonary edema nor venous congestion is seen radiographically and if the resting respiratory rate has not increased. Left mainstem bronchus compression by an enlarged LA can stimulate a dry cough. Cough suppressants are helpful for this, but they should be prescribed only after other causes of cough are ruled out.

Echocardiography may show evidence of chordal rupture, progressive cardiomegaly, or worsened myocardial function. Frequent monitoring of serum electrolyte concentrations and renal function is important. Other routine blood and urine tests are done periodically also. Dogs receiving digoxin should have a serum concentration measured 7 to 10 days after treatment initiation or a dosage change. Additional measurements are recommended if signs consistent with toxicity appear or if renal disease or electrolyte imbalance (hypokalemia) is suspected.

The prognosis in dogs that have shown clinical signs of degenerative valve disease is quite variable. With appropriate therapy and attentive management of complications, some dogs live well for more than 4 years after the signs of heart failure first appear. Some dogs die during an initial episode of fulminant pulmonary edema. Survival for most symptomatic dogs ranges from several months to a few years.

# INFECTIVE ENDOCARDITIS

# **Etiology and Pathophysiology**

Endocarditis is more common in dogs than in cats. Bacteremia, either persistent or transient, is necessary for endocardial infection to occur. Recurrent bacteremia may occur with infections of the skin, mouth, urinary tract, prostate, lungs, or other organs. Dentistry procedures are known to cause a transient bacteremia. Other procedures are presumed to cause transient bacteremia in some cases (e.g., endoscopy, urethral catheterization, anal surgery, and other "dirty" procedures). The likelihood of a cardiac infection becoming established is increased when organisms are highly virulent or the bacterial load is heavy.

The endocardial surface of the valve is infected directly from the blood flowing past it. Previously normal valves may be invaded by virulent bacteria, causing acute bacterial endocarditis. Subacute bacterial endocarditis is thought to result from infection of previously damaged or diseased valves after a persistent bacteremia. Such damage may result from mechanical trauma (e.g., jet lesions resulting from turbulent blood flow or endocardial injury from a vascular catheter extending into the heart). Myxomatous degeneration of the mitral valve has not been associated with a higher risk for infective endocarditis.

The lesions of endocarditis are typically located downstream from the disturbed blood flow; common sites include the ventricular side of the aortic valve in patients with subaortic stenosis, the right ventricular side of a ventricular septal defect, and the atrial surface of a regurgitant mitral valve. Bacterial clumping caused by the action of an agglutinating antibody may facilitate attachment to the valves. Alternatively, chronic stress and mechanical trauma can predispose to the development of nonbacterial thrombotic endocarditis, a sterile accumulation of platelets and fibrin on the valve surface. Nonseptic emboli may break off from such vegetations and cause infarctions elsewhere. Bacteremia can also cause a secondary infective endocarditis at these sites.

The most common organisms identified in dogs and cats with endocarditis have been *Streptococcus* sp., *Staphylococcus* sp., and *Escherichia coli*. Additional organisms isolated from infected valves have included *Corynebacterium* (*Arcanobacterium*) sp., *Pasteurella* sp., *Pseudomonas aeruginosa*, *Erysipelothrix rhusiopathiae* (*E. tonsillaris*), and others. *Bartonella vinsonii* subsp. *berkhoffii* and other *Bartonella* sp. have also been found in dogs with endocarditis. Culture-negative endocarditis may be caused by fastidious organisms or by *Bartonella* spp.; in a recent study of 71 dogs with infective endocarditis, *Bartonella* spp. was identified as the causative agent in 45% of the patients with a negative blood culture and in 20% of the overall population.

The mitral and aortic valves are most commonly affected in dogs and cats. Microbial colonization leads to ulceration of the valve endothelium. Subendothelial collagen exposure in turn stimulates platelet aggregation and activation of the coagulation cascade, leading to the formation of vegetations. Vegetations consist mainly of aggregated platelets, fibrin, blood cells, and bacteria. Newer vegetations are friable. With time, the lesions become fibrous and may calcify. As additional fibrin is deposited over bacterial colonies, they become protected from normal host defenses as well as many antibiotics. Although vegetations usually involve the valve leaflets, lesions may extend to the chordae tendineae, sinuses of Valsalva, mural endocardium, or adjacent myocardium. Vegetations cause valve deformity, including perforations or tearing of the leaflet(s), and result in valve insufficiency. Rarely, large vegetations may cause the valve to become stenotic.

Valve insufficiency and subsequent volume overload commonly lead to CHF. Because the mitral and/or aortic valve is usually affected, left-sided CHF signs of pulmonary congestion and edema are usual. Clinical heart failure develops rapidly in patients with severe valve destruction, rupture of chordae tendineae, and multiple valve involvement, or when other predisposing factors are present. Cardiac function can be compromised by myocardial injury resulting from coronary arterial embolization with myocardial infarction and abscess formation or from direct extension of the infection into the myocardium. Reduced contractility and atrial or ventricular tachyarrhythmias often result. Aortic valve endocarditis lesions may extend into the AV node and cause partial or complete AV block. Arrhythmias may cause weakness, syncope, and sudden death or contribute to the development of CHF.

Fragments of vegetative lesions often break loose. Embolization of other body sites causes infarction or metastatic infection, which results in diverse clinical signs. Larger and more mobile vegetations (based on echocardiographic appearance) are associated with higher incidence of embolic events in people; the same may occur in animals. Emboli can be septic or bland (containing no infectious organisms). Septic arthritis, diskospondylitis, urinary tract infections, and renal and splenic infarctions are common in affected animals. Local abscess formation resulting from septic thromboemboli contributes to recurrent bacteremia and fever. Hypertrophic osteopathy has also been associated with bacterial endocarditis. Circulating immune complexes as well as cell-mediated responses contribute to the disease syndrome. Sterile polyarthritis, glomerulonephritis, vasculitis, and other forms of immune-mediated organ damage are common. Rheumatoid factor and antinuclear antibody test (ANA) results may be positive.

#### **Clinical Features**

The prevalence of bacterial endocarditis is relatively low in dogs and even lower in cats. Male dogs are affected more commonly than females. An increased prevalence of endocarditis has been noted in association with age. German Shepherd Dogs and other large-breed dogs may be at greater risk. Subaortic stenosis is a known risk factor for aortic valve endocarditis. Immunocompromised animals may also be at greater risk for endocarditis, but this has not been substantiated.

The clinical signs of endocarditis are quite variable. Many affected animals have evidence of past or concurrent infections, although often a clear history of predisposing factors is absent. The presenting signs can result from left-sided CHF or arrhythmias, but cardiac signs may be overshadowed by signs of systemic infarction, infection, immune-mediated damage, or a combination of these. Nonspecific signs of lethargy, weight loss, inappetence, recurrent fever, and weakness may be the predominant abnormalities. Infective endocarditis often mimics immune-mediated disease. Dogs with endocarditis are commonly evaluated for a "fever of unknown origin." Some of the consequences of infectious endocarditis are outlined in Box 6-3. Endocarditis has been nicknamed "the great imitator"; maintaining an index of suspicion for this disease is important.

BOX 6-3

# Potential Sequelae of Infective Endocarditis

#### Heart

Valve insufficiency or stenosis

Murmur

Congestive heart failure

Coronary embolization (aortic valve\*)

Myocardial infarction Myocardial abscess Myocarditis

Decreased contractility (segmental or global)

Arrhythmias

Myocarditis (direct invasion by microorganisms)

**Arrhythmias** 

Atrioventricular conduction abnormalities (aortic valve\*)

Decreased contractility

Pericarditis (direct invasion by microorganisms)

Pericardial effusion Cardiac tamponade (?)

#### Kidney

Infarction

Reduced renal function

Abscess formation and pyelonephritis

Reduced renal function Urinary tract infection

Renal pain

Glomerulonephritis (immune mediated)

Proteinuria

Reduced renal function

Malaise and depression

Shaking

Vague pain

Inflammatory leukogram

Mild anemia

± Positive antinuclear antibody test

± Positive blood cultures

Infective valve damage may be signaled by signs of CHF in an unexpected clinical setting or in an animal with a murmur of recent onset, especially if other suggestive signs are present. But a "new" murmur can indicate noninfective acquired disease (e.g., degenerative valve disease, cardiomyopathy), previously undiagnosed congenital disease, or physiologic alterations (e.g., fever, anemia). Conversely, endocarditis may develop in an animal known to have a murmur resulting from another cardiac disease. Although a change in murmur quality or intensity over a short time frame may indicate active valve damage, physiologic causes of murmur variation are common. The onset of a diastolic murmur at the left heartbase is suspicious for aortic valve endocarditis, especially if fever or other signs are present.

# Diagnosis

It may be difficult to obtain a definitive antemortem diagnosis. Presumptive diagnosis of infective endocarditis is made on the basis of positive findings in two or more blood cultures, in addition to either echocardiographic evidence of vegetations or valve destruction or the documented recent appearance of a regurgitant murmur. Endocarditis is likely even when blood culture results are negative or intermittently positive if there is echocardiographic evidence of vegetations or valve destruction along with a combination of other criteria (Box 6-4). A new diastolic murmur, hyperkinetic pulses, and fever are strongly suggestive of aortic valve endocarditis.

Several samples of at least 10 ml of blood should be aseptically collected over a 24-hour period for bacterial blood

<sup>\*</sup> Diseased valve most commonly associated with abnormality.

Criteria for Diagnosis of Infectious Endocarditis\*

#### **Definite Endocarditis by Pathologic Criteria**

Pathologic (postmortem) lesions of active endocarditis with evidence of microorganisms in vegetation (or embolus) or intracardiac abcess

#### **Definite Endocarditis by Clinical Criteria**

Two major criteria (below), or One major and three minor criteria, or Five minor criteria

#### **Possible Endocarditis**

Findings consistent with infectious endocarditis that fall short of "definite" but not "rejected"

#### Rejected Diagnosis of Endocarditis

Firm alternative diagnosis for clinical manifestations
Resolution of manifestations of infective endocarditis with 4
or fewer days of antibiotic therapy

No pathologic evidence of infective endocarditis at surgery or necropsy after 4 or fewer days of antibiotic therapy

#### **Major Criteria**

Positive blood cultures

Typical microorganism for infective endocarditis from two separate blood cultures Persistently positive blood cultures for organism consistent with endocarditis (samples drawn >12 h apart or three or more cultures drawn at least 1 h apart)

Evidence of endocardial involvement

Positive echocardiogram for infective endocarditis (oscillating mass on heart valve or supportive structure or in path of regurgitant jet or evidence of cardiac abcess). New valvular regurgitation (increase or change in preexisting murmur not sufficient evidence).

#### **Minor Criteria**

Predisposing heart condition (see p. 126)

Vascular phenomena: major arterial emboli, septic infarcts Immunologic phenomena: glomerulonephritis, positive antinuclear antibody or rheumatoid factor tests

Microbiologic evidence: positive blood culture not meeting major criteria above

Echocardiogram consistent with infective endocarditis but not meeting major criteria above

(Rare in dogs and cats: repeated nonsterile IV drug administration)

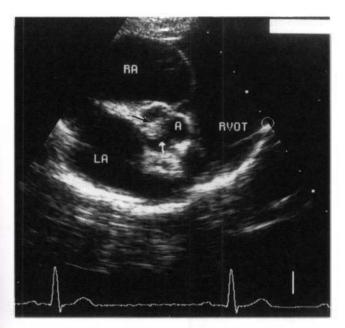

\* Adapted from Duke criteria for endocarditis. In Durack DT et al: New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings, Am J Med 96:200, 1994.

culture, with more than 1 hour elapsing between collections. Ideally, different venipuncture sites should be used for each sample. Larger sample volumes (e.g., 20 to 30 ml) increase culture sensitivity. Both aerobic and anaerobic cultures have been recommended, although the value of routine anaerobic culture is questionable. Prolonged incubation (3 weeks) is recommended because some bacteria are slow-growing. Although blood culture results are positive in many dogs with this disease, negative results do not necessarily rule out infective endocarditis; in a recent study, less than 50% of the blood cultures in dogs with confirmed infective endocarditis were positive. As discussed above, Bartonella spp. is an emerging pathogen that causes blood culture-negative endocarditis in dogs; in the same study, 45% of the dogs with negative blood cultures were positive for Bartonella spp. on polymerase chain reaction (PCR). Results may be negative in the setting of chronic endocarditis, recent antibiotic therapy, intermittent bacteremia, and infection with fastidious or slow-growing organisms, as well as noninfective endocarditis. Serologic and PCR testing are also commercially available for Bartonella spp.

Echocardiography is especially supportive if oscillating vegetative lesions and abnormal valve motion can be identified (Fig. 6-4). The visualization of lesions depends on their size and location, on the image resolution, and

the proficiency of the echocardiographer. Because falsenegative and false-positive findings of "lesions" may occur, cautious interpretation of images is important. Mild valve thickening and/or enhanced echogenicity may occur in patients with early valve damage. Vegetative lesions appear as irregular dense masses. As valve destruction progresses, ruptured chordae, flail leaflet tips, or other abnormal valve motion can be seen. Differentiation of mitral vegetations from degenerative thickening may be impossible, however, especially in the early stages. Nevertheless, vegetative endocarditis classically causes rough, ragged-looking valve thickening; degenerative disease is associated with smooth valvular thickening. Poor or marginal-quality images or the use of lower-frequency transducers can prevent identification of some vegetations because of suboptimal resolution. Secondary effects of valve dysfunction include chamber enlargement from volume overload and flail or otherwise abnormal valve leaflet motion. Myocardial dysfunction and arrhythmias may also be evident. Aortic insufficiency can cause fluttering of the anterior mitral valve leaflet during diastole as the regurgitant jet makes contact with this leaflet. Doppler studies illustrate flow disturbances (Fig. 6-5).

The ECG may be normal or document premature beats, tachycardias, conduction disturbances, or evidence of myo-

#### FIG 6-4

Right parasternal short-axis echocardiogram at the aortic-left atrial level in a 2-year-old male Vizsla with congenital subaortic stenosis and pulmonic stenosis. Note the aortic valve vegetation (arrows) caused by endocarditis. A, Aorta; LA, left atrium; RA, right atrium; RVOT, right ventricular outflow tract.

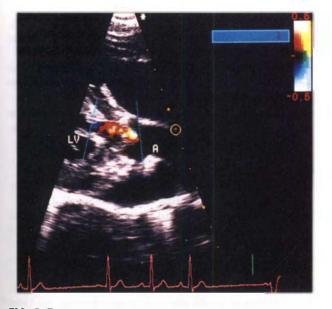

FIG 0-5

cardial ischemia. Radiographic findings are unremarkable in some cases; however, in others, evidence of left-sided CHF or other organ involvement (e.g., diskospondylitis) is seen. Cardiomegaly is minimal early in the disease but progresses over time as a result of valve insufficiency.

Clinicopathologic findings usually reflect an inflammatory process. Neutrophilia with a left shift is typical of acute endocarditis, whereas mature neutrophilia with or without monocytosis usually develops with chronic disease. Nonregenerative anemia has been associated with about half of canine cases. Biochemical abnormalities are variable. Azotemia, hyperglobulinemia, hematuria, pyuria, and proteinuria are common. The ANA results may be positive in dogs with subacute or chronic bacterial endocarditis; in a recent study, 75% of dogs with *Bartonella vinsonii* infection had positive ANA test results.

# **Treatment and Prognosis**

Aggressive therapy with bactericidal antibiotics capable of penetrating fibrin, as well as supportive care, are indicated for infective endocarditis. Ideally, drug choice is guided by culture and in-vitro susceptibility test results. Because treatment delay while waiting for these results can be harmful, broad-spectrum combination therapy is usually begun immediately after blood culture samples are obtained. Therapy can be altered, if necessary, when culture results are available. Culture-negative cases should be continued on the broad-spectrum regimen. An initial combination of a cephalosporin, penicillin, or a synthetic penicillin derivative (e.g., ampicillin) with an aminoglycoside (gentamicin or amikacin) or a fluoroquinolone (e.g. enrofloxacin) is commonly used. This is likely to be effective against the organisms most often associated with infective endocarditis. Clindamycin or metronidazole provides added anaerobic efficacy. Azithromycin or possibly enrofloxacin or high-dose doxycycline has been suggested for Bartonella spp.

Antibiotics are administered intravenously (or at least intramuscularly) for the first week or longer to obtain higher and more predictable blood concentrations. Oral therapy is often used thereafter for practical reasons, although parenteral administration is probably better. Antimicrobial therapy is continued for at least 6 weeks; 8 weeks of therapy is often recommended. However, aminoglycosides are discontinued after 1 week or sooner if renal toxicity develops. Close monitoring of the urine sediment is indicated to detect early aminoglycoside nephrotoxicity. For documented or suspected *B. vinsonii* (berkhoffii) infection, repeat serologic or PCR testing is recommended between 3 and 6 months after antibiotic therapy.

Supportive care includes management for CHF (see Chapter 3) and arrhythmias (see Chapter 4) if present. Complications related to the primary source of infection, embolic events, or immune responses are addressed to the extent possible. Attention to hydration status, nutritional support, and general nursing care is also important. Corticosteroids are contraindicated. The efficacy of aspirin to inhibit platelet aggregation and vegetative lesion growth and reduce the risk of embolic events is unknown. Aspirin or oral anticoagulants appear to be of no benefit for this in people.

Long-term prognosis is generally guarded to poor. Echocardiographic evidence of vegetations and volume overload suggests a poor prognosis. Aggressive therapy may be successful if valve dysfunction is not severe and large vegetations are absent. CHF is the most common cause of death, although sepsis, systemic embolization, arrhythmias, or renal failure may be the proximate cause.

The use of prophylactic antibiotics is controversial. Experience in people indicates that most cases of infective endocarditis are not preventable. The risk of endocarditis from a specific (e.g., dental) procedure in humans is very low compared with the cumulative risk associated with normal daily activities. However, because endocarditis appears to have an increased incidence in patients with certain cardiovascular malformations, antimicrobial prophylaxis is recommended before dental or other "dirty" procedures (e.g., involving the oral cavity or intestinal or urogenital systems) in these cases. Subaortic stenosis is a well-recognized predisposing lesion; endocarditis has also been associated with ventricular septal defect, patent ductus arteriosus, and cyanotic congenital heart disease. Antimicrobial prophylaxis is recommended for animals with an implanted pacemaker or other device or with a history of endocarditis. Prophylaxis should be considered for immunocompromised animals as well. Recommendations (extrapolated from human medicine) include the administration of high-dose ampicillin or amoxicillin 1 hour before and 6 hours after an oral or upper respiratory procedure and ampicillin with an aminoglycoside (IV, 30 minutes before and 8 hours after) a gastrointestinal or urogenital procedure. Alternatively, ticarcillin or a first-generation cephalosporin intravenously 1 hour before and 6 hours after the procedure has been used.

Infective Myocarditis

Non-Infective Myocarditis

Traumatic Myocarditis

Heart muscle disease that leads to contractile dysfunction and cardiac chamber enlargement is an important cause of heart failure in dogs. Idiopathic or primary dilated cardiomyopathy (DCM) is most common and mainly affects the larger breeds. Secondary and infective myocardial diseases (see pp. 135 and 137) occur less often. Arrhythmogenic right ventricular cardiomyopathy (ARVC), also known as Boxer cardiomyopathy, is an important myocardial disease in Boxers. ARVC is uncommon in other breeds. Hypertrophic cardiomyopathy (HCM) is recognized infrequently in dogs (see p. 137).

# DILATED CARDIOMYOPATHY

# **Etiology and Pathophysiology**

DCM is an idiopathic disease characterized by poor myocardial contractility, with or without arrhythmias. A genetic basis is thought to exist for idiopathic DCM, especially in breeds that have a high prevalence or a familial occurrence of the disease. Large and giant breeds are most commonly affected, including Doberman Pinschers, Great Danes, Saint Bernards, Scottish Deerhounds, Irish Wolfhounds, Boxers, Newfoundlands, Afghan Hounds, and Dalmatians. Some smaller breeds such as Cocker Spaniels and Bulldogs are also affected. The disease in rarely seen in dogs that weigh less than 12 kg. In at least some Great Danes, DCM appears to be an X-linked recessive trait. An autosomal dominant inheritance pattern was found in Boxers with ventricular arrhythmias (discussed in more detail later in this chapter); however, a rapidly fatal familial DCM affecting very young Portuguese Water Dogs shows an autosomal recessive inheritance pattern. Doberman Pinschers appear to have the highest prevalence of DCM; although a genetic basis is suspected, the inheritance pattern is not clear.

Various biochemical defects, nutritional deficiencies, toxins, immunologic mechanisms, and infectious agents may be involved in the pathogenesis of DCM in different cases. Impaired intracellular energy homeostasis and decreased myocardial adenosine triphosphate (ATP) concentrations were found in myocardial biochemical studies of affected Doberman Pinschers. DCM as an entity probably represents the end-stage of different pathologic processes or metabolic defects involving myocardial cells or the intercellular matrix rather than a single disease. Idiopathic DCM has also been associated with prior viral infections in people. However, on the basis of polymerase chain reaction (PCR) analysis of myocardial samples from a small number of DCM-affected dogs, viral agents do not seem to be commonly associated with DCM in this species.

Decreased ventricular contractility (systolic dysfunction) is the major functional defect in dogs with DCM. Progressive cardiac chamber dilation (remodeling) develops as systolic pump function and cardiac output worsen and compensa-

tory mechanisms become activated. Poor cardiac output can cause weakness, syncope, and ultimately, cardiogenic shock. Increased diastolic stiffness also contributes to the development of higher end-diastolic pressures, venous congestion, and congestive heart failure (CHF). Cardiac enlargement and papillary muscle dysfunction often cause poor systolic apposition of mitral and tricuspid leaflets with valve insufficiency. Although severe degenerative atrioventricular (AV) valve disease is not typical in dogs with DCM, some have mild to moderate valvular disease, which exacerbates valve insufficiency.

As cardiac output decreases, sympathetic, hormonal, and renal compensatory mechanisms become activated. These mechanisms increase heart rate, peripheral vascular resistance, and volume retention (see Chapter 3). Chronic neurohormonal activation is thought to contribute to progressive myocardial damage, as well as to CHF. Coronary perfusion can be compromised by poor forward blood flow and increased ventricular diastolic pressure; myocardial ischemia further impairs myocardial function and predisposes to arrhythmia development. Signs of low-output heart failure and right- or left-sided CHF (see Chapter 3) are common in dogs with DCM.

Atrial fibrillation (AF) often develops in dogs with DCM. Atrial contraction contributes importantly to ventricular filling, especially at faster heart rates. The loss of the "atrial kick" associated with AF reduces cardiac output and can cause acute clinical decompensation. Persistent tachycardia associated with AF probably also accelerates disease progression. Ventricular tachyarrhythmias also occur frequently and can cause sudden death. In Doberman Pinschers serial Holter recordings have documented the appearance of ventricular premature contractions (VPCs) months to more than a year before early echocardiographic abnormalities were noted. Once left ventricular (LV) function begins to deteriorate, the frequency of tachyarrhythmias increases. Excitement-induced bradyarrhythmias have also been associated with low-output signs in Doberman Pinschers.

Dilation of all cardiac chambers is typical in dogs with DCM, although left atrial (LA) and LV enlargement usually predominate. The ventricular wall thickness may appear decreased compared with the lumen size. Flattened, atrophic papillary muscles and endocardial thickening are described. Concurrent degenerative changes of the AV valves are generally only mild to moderate, if present at all. Histopathologic findings include scattered areas of myocardial necrosis, degeneration, and fibrosis, especially in the left ventricle. Narrowed (attenuated) myocardial cells with a wavy appearance may be a common finding. Inflammatory cell infiltrates, myocardial hypertrophy, and fatty infiltration (mainly in Boxers and some Doberman Pinschers) are inconsistent features.

# **Clinical Findings**

The prevalence of DCM increases with age, although most dogs presented with CHF are 4 to 10 years old. Males appear to be affected more often than females. However, in Boxers

and Doberman Pinschers there may be no gender predilection once dogs with occult disease are included. Cardiomyopathy in Boxers is described in more detail later (see p. 134). Male Doberman Pinschers generally show signs at an earlier age than females.

DCM appears to develop slowly, with a prolonged preclinical (occult) stage that may evolve over several years before clinical signs become evident. Occult DCM often is recognized through the use of echocardiography. Some giant-breed dogs with mild-to-moderate LV dysfunction are relatively asymptomatic, even in the presence of AF.

Clinical signs of DCM may appear to develop rapidly, especially in sedentary dogs in which early signs may not be noticed. Sudden death before CHF signs develop is relatively common. Presenting complaints include any or all of the following: weakness, lethargy, tachypnea or dyspnea, exercise intolerance, cough (sometimes described as "gagging"), anorexia, abdominal distention (ascites), and syncope (see Fig. 1-2). Loss of muscle mass (cardiac cachexia), accentuated along the dorsal midline, may be severe.

Physical examination findings vary with the degree of cardiac decompensation. Dogs with occult disease may have a normal physical exam. Others have a soft murmur of mitral or tricuspid regurgitation or an arrhythmia. Dogs with advanced disease and poor cardiac output have increased sympathetic tone and peripheral vasoconstriction. A consequence is mucous membrane pallor and slowed capillary refill time. The femoral arterial pulse and precordial impulse are often weak and rapid. Uncontrolled AF and frequent VPCs cause an irregular and usually rapid heart rhythm, with frequent pulse deficits and variable pulse strength (see Fig. 4-1). Signs of left- and/or right-sided CHF include tachypnea, increased breath sounds, pulmonary crackles, jugular venous distention or pulsations, pleural effusion or ascites, and/or hepatosplenomegaly. Heart sounds may be muffled in association with pleural effusion or poor cardiac contractility. An audible third heart sound (S<sub>3</sub> gallop) is a classic finding, although it may be obscured by an irregular heart rhythm. Systolic murmurs of mitral or tricuspid regurgitation that are soft to moderate in intensity are common.

# Diagnosis

#### RADIOGRAPHY

The stage of disease, chest conformation, and hydration status influence the radiographic findings. Generalized cardiomegaly is usually evident, although left heart enlargement may predominate (Fig. 7-1). In Doberman Pinschers the heart may appear minimally enlarged, except for the left atrium. In other dogs cardiomegaly may be severe and can mimic the globoid cardiac silhouette typical of large pericardial effusions. Distended pulmonary veins and pulmonary interstitial or alveolar opacities, especially in the hilar and dorsocaudal regions, accompany left heart failure with pulmonary edema. The distribution of pulmonary edema infiltrates may be asymmetric or widespread. Pleural effusion,

caudal vena cava distention, hepatomegaly, and ascites usually accompany right-sided CHF.

# **ELECTROCARDIOGRAPHY**

The electrocardiogram (ECG) findings in dogs with DCM are also variable. Sinus rhythm is usually the underlying

rhythm, although AF is often documented instead, especially in Great Danes and other giant breeds (see Fig. 2-11). Other atrial tachyarrhythmias, paroxysmal or sustained ventricular tachycardia, fusion complexes, and multiform VPCs are frequent findings. The QRS complexes may be tall (consistent with LV dilation), normal size, or small. Myocardial disease

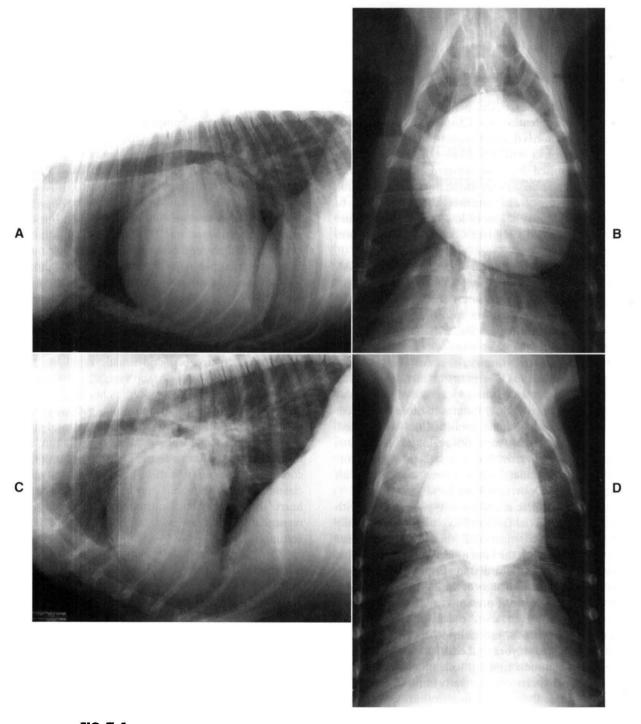

FIG 7-1

Radiographic examples of dilated cardiomyopathy in dogs. Lateral (A) and dorsoventral (B) views showing generalized cardiomegaly in a male Labrador Retriever. Note the cranial pulmonary vein is slightly larger than the accompanying artery in (A). Lateral (C) and dorsoventral (D) views of Doberman Pinscher depicting the prominent left atrial and relatively moderate ventricular enlargements commonly found in affected dogs of this breed. There is mild peribronchial pulmonary edema as well.

often causes a widened QRS complex with a slowed R-wave descent and slurred ST segment. A bundle-branch block pattern or other intraventricular conduction disturbance may be observed. The P waves in dogs with sinus rhythm are frequently widened and notched, suggesting LA enlargement.

Twenty-four-hour Holter monitoring is useful for documenting frequent ventricular ectopy. This has been used as a screening tool for cardiomyopathy in Doberman Pinschers and Boxers (see p. 135). The presence of >50 VPCs/day or any couplets or triplets is thought to predict future overt DCM in Doberman Pinschers. Nevertheless, some dogs with <50 VPCs/day on initial evaluation may develop DCM after several years. The frequency and complexity of ventricular tachyarrhythmias appear to be negatively correlated with fractional shortening; sustained ventricular tachycardia has been associated with increased risk of sudden death. Variability in the number of VPCs between repeated Holter recordings in the same dog can be high. If available, the technique of signal averaged electrocardiography can reveal the presence of ventricular late potentials, which may suggest an increased risk for sudden death in Doberman Pinschers with occult DCM.

#### **ECHOCARDIOGRAPHY**

Echocardiography is used to assess cardiac chamber dimensions and myocardial function and differentiate pericardial effusion or chronic valvular insufficiency from DCM. Dilated cardiac chambers and poor systolic ventricular wall and septal motion are characteristic findings in dogs with DCM. In severe cases only minimal wall motion is evident. All chambers are usually affected, but right atrial (RA) and right ventricular (RV) dimensions may appear normal, especially in Doberman Pinschers and Boxers. LV systolic (as well as diastolic) dimension is increased compared with normal ranges for the breed, and the ventricle appears more spherical. Fractional shortening and ejection fraction are decreased (Fig. 7-2). Other common features are a wide mitral valve E point-septal separation and reduced aortic root motion. LV free-wall and septal thicknesses are normal to decreased. The calculated end-systolic volume index (see p. 41) is generally over 80 ml/m<sup>2</sup> in dogs with overt DCM (<30 ml/m<sup>2</sup> is considered normal). Evidence for abnormal diastolic as well as systolic function can be found in dogs with advanced disease. Mild to moderate AV valve regurgitation is usually seen with Doppler echocardiography (Fig. 7-3).

Echocardiography is also used to screen for occult disease. There may be no clear abnormalities early in the disease. Alternatively, apparently healthy Doberman Pinschers may have slightly reduced fractional shortening compared with what is considered normal for other breeds. The following echocardiographic criteria appear to indicate high risk for overt DCM within 2 to 3 years in asymptomatic Doberman Pinschers: LVIDd >46 mm (in dogs <42 kg) or >50 mm (in dogs >42 kg), LVIDs >38 mm, or VPCs during initial examination, FS < 25%, and/or mitral valve E point–septal separation >8 mm (*LVID*, left ventricular internal diameter; *d*, diastole; *s*, systole).

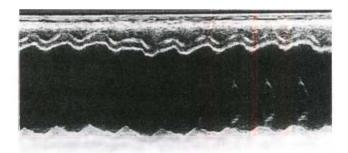

FIG 7-2
M-mode echocardiogram from a dog with dilated cardiomyopathy at the chordal (left side of figure) and mitral valve
(right side of figure) levels. Note attenuated wall motion
(fractional shortening = 18%) and the wide mitral valve E
point-septal separation (28 mm).

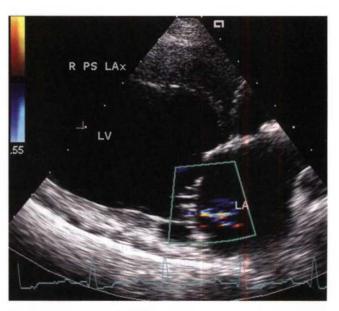

FIG 7-3
Mild mitral regurgitation is indicated by a relatively small area of disturbed flow in this systolic frame from a Standard Poodle with dilated cardiomyopathy. Note the LA and LV dilation. Right parasternal long axis view, optimized for the left ventricular inflow tract. LA, Left atrium; LV, left ventricle.

# **CLINICOPATHOLOGIC FINDINGS**

Clinicopathologic findings are noncontributory in most cases. In others, prerenal azotemia resulting from poor renal perfusion or mildly increased liver enzyme activities resulting from passive hepatic congestion occur. Severe CHF may be associated with hypoproteinemia, hyponatremia, and hyperkalemia. Hypothyroidism with associated hypercholesterolemia occurs in some dogs with DCM. Others have a reduced serum thyroid hormone concentration without hypothyroidism (sick euthyroid); normal TSH and free T<sub>4</sub> concentrations are common. Increased circulating neurohormones (e.g., norepiniphrine, aldosterone, endothelin, natriuretic peptides) occur mainly in DCM dogs with overt CHF. Natriuretic peptide elevations in dogs with occult DCM are also reported in some studies. Significant positive

correlations have been identified between LV dimensions (in both diastole and systole) and atrial natriuretic peptide, as well as endothelin (O'Sullivan et al., 2007). Neurohormonal changes in occult DCM were not associated with time to CHF onset or sudden death in this study; however, in dogs with overt CHF, increases in NE and endothelin over a month were inversely associated with survival time. Serum cardiac troponin (cTnT or cTnI) concentrations are elevated in some dogs with DCM, as well as with other causes of myocyte injury.

#### Treatment

# OCCULT DILATED CARDIOMYOPATHY

Dogs with LV dilation or reduced FS are often treated with an angiotensin-converting enzyme inhibitor (ACEI), although it is unclear whether this prolongs the preclinical phase. Other therapy aimed at modulating early neurohormonal responses and ventricular remodeling processes have theoretical appeal, but their clinical usefulness is not clear. Further study of this using certain  $\beta$ -blockers (e.g., carvedilol, metoprolol), spironolactone, pimobendan, and other agents is ongoing.

The decision to use antiarrhythmic drug therapy in dogs with ventricular tachyarrhythmias is influenced by whether they result in clinical signs (e.g., episodic weakness, syncope) as well as the arrhythmia frequency and complexity seen on Holter recording. Various antiarrhythmic agents have been used, but the most effective regimen(s) and when to institute therapy are still not clear. It would seem that a regimen that increases ventricular fibrillation threshold and decreases arrhythmia frequency and severity is desired. Sotalol, amiodarone (both Class III agents), as well as the combination of mexiletine and atenolol or procainamide with atenolol, may be useful.

# CLINICALLY EVIDENT DILATED CARDIOMYOPATHY

Therapy is aimed at improving the animal's quality of life and prolonging survival to the extent possible by controlling CHF signs, optimizing cardiac output, and managing arrhythmias. Pimobendan (or digoxin), an ACEI, and furosemide are used for most dogs (Box 7-1). Severe heart failure may require additional therapy, including an intravenous (IV) inotropic agent. Antiarrhythmic drugs are used on the basis of individual need.

Dogs with acute CHF are treated as outlined in Box 3-1, with parenteral furosemide, supplemental oxygen, 2% nitroglycerin ointment or sodium nitroprusside infusion, inotropic support, and cage rest, with or without aminophylline and morphine or butorphanol. Thoracocentesis is indicated if pleural effusion is suspected or identified.

Inotropic support can be in the form of oral pimobendan and/or digoxin if oral administration is not overly stressful and the delay in onset of effects is not critical. More acute and stronger inotropic support for dogs with very poor contractility, persistent hypotension, or fulminant CHF can be

Treatment Outline for Dogs with Dilated Cardiomyopathy

#### Mild to Moderate Signs of Congestive Heart Failure\*

ACEI

Furosemide

Pimobendan (or digoxin)

Antiarrhythmic therapy, if necessary

+/- Initiate spironolactone

Complete exercise restriction until signs abate

Moderate dietary salt restriction

#### Severe, Acute Signs of Congestive Heart Failure\*

Supplemental O<sub>2</sub>

Furosemide (parenteral)

Inotropic support (e.g., IV dobutamine and/or amrinone with minimal fluid volume; initiate oral pimobendan [or digoxin] when possible)

ACEI as soon as possible

Other vasodilator with caution (e.g., IV nitroprusside, oral hydralazine, or amlodipine with topical nitroglycerine)

Antiarrhythmic therapy, if necessary\*\* (With uncontrolled AF, catecholamine infusion can further increase AV conduction and ventricular response rate; if dopamine or dobutamine is necessary, use IV diltiazem or digoxin [either by oral route or cautious IV loading])

+/- Bronchodilator

+/- Butorphanol or morphine

Cage rest

Minimize patient handling

Monitor respiratory rate, heart rate and rhythm, arterial blood pressure, peripheral perfusion, urine output, renal function, serum electrolytes, etc.

#### AF and Inadequate Heart Rate Control with Digoxin\*\*

Acute: add IV diltiazem

Chronic: add oral β-blocker at low dose or diltiazem; titrate to effect

#### Chronic Dilated Cardiomyopathy Management\*

ACE

Furosemide (lowest effective dosage and frequency)

Pimobendan/digoxin

Spironolactone

Antiarrhythmic therapy as indicated

+/- Other medications (see p. 67)

+/- Carvedilol/metoprolol

Client education

Resting respiratory rate (and heart rate if possible) monitoring at home

Regular but mild exercise

Dietary salt restriction

Routine health maintenance (including heartworm testing and prophylaxis in endemic areas)

Proper management of other medical problems

ACEI, Angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; AV, atrioventricular.

<sup>\*</sup> See text and Chapter 3 for further details.

<sup>\*\*</sup>See Chapter 4, p. 81.

provided by IV infusion of dobutamine or dopamine for 2 (to 3) days. The phosphodiesterase inhibitors amrinone and milrinone may be helpful for short-term stabilization in some dogs and can be used concurrently with digoxin and a catecholamine. Long-term use of strong positive inotropic drugs is thought to have detrimental effects on the myocardium. During infusion of these drugs, the animal must be observed closely for worsening tachycardia or arrhythmias (especially VPCs).

If arrhythmias develop, the drug is discontinued or infused at up to half the original rate. In dogs with AF, catecholamine infusion is likely to increase the ventricular response rate because the drug enhances AV conduction. If dopamine or dobutamine is thought necessary in dogs with AF, rapid oral or cautious IV diltiazem can be used to slow AV conduction. Digoxin, either administered orally or by cautious IV loading doses, is an alternative.

Because clinical status may deteriorate rapidly, frequent patient evaluation is important. Respiratory rate and character, lung sounds, pulse quality, heart rate and rhythm, peripheral perfusion, rectal temperature, hydration status, body weight, renal function, mentation, pulse oxymetry, and blood pressure should be monitored. Ventricular contractility is abysmal in many dogs with severe DCM; because these patients have little cardiac reserve, diuretic and vasodilator therapy may lead to hypotension, and even cardiogenic shock.

# Long-Term Therapy

Chronic inotropic therapy for dogs with DCM traditionally consisted of oral digoxin, but pimobendan now offers several advantages over digoxin (see p. 65). Pimobendan (Vetmedin, Boehringer Ingelheim) is a phosphodiesterase III inhibitor that increases contractility through a Ca<sup>++</sup>-sensitizing effect; the drug also has vasodilator and other beneficial effects. Digoxin, with its neurohormonal modulating and antiarrhythmic effects, may still be useful and can be given with pimobendan. Digoxin is indicated in dogs with AF to help slow the ventricular response rate. It can also suppress some other supraventricular tachyarrhythmias.

If digoxin is used, it is generally initiated with oral maintenance doses. Toxicity seems to develop at relatively low dosages in some dogs, especially Doberman Pinschers. A total maximum daily dose of 0.5 mg is generally used for large and giant-breed dogs, except for Doberman Pinschers, which are given a total maximum dose of 0.25 mg/day to 0.375 mg/day. Serum digoxin concentration should be measured 7 to 10 days after digoxin therapy is initiated or the dose is changed (see p. 66). Dogs with AF and a ventricular rate exceeding 200 beats/min can be cautiously given digoxin IV (see Box 3-1) or twice the oral maintenance dose on the first day to more rapidly achieve effective blood concentrations. However, the use of IV or rapid oral diltiazem is probably safer (see p. 81). If oral digoxin alone has not significantly reduced the heart rate after 36 to 48 hours, a β-blocker or diltiazem may be added (see Table 4-2). Because these agents can have negative inotropic effects, a low initial dose and gradual dosage titration to effect or a maximum recommended level is advised. Heart rate control in dogs with AF is important. A maximum ventricular rate of 140 to 150 beats/min in the hospital (i.e., stressful) setting is the recommended target; lower heart rates (c.g., ~100 beats/min or less) are expected at home. Because accurate counting of heart rate by auscultation or chest palpation in dogs with AF is difficult, an ECG recording is recommended. Femoral pulses should not be used to assess heart rate in the presence of AF.

Furosemide is used at the lowest effective oral dose and at consistent time intervals for long-term therapy (see Table 3-3). Hypokalemia and alkalosis are uncommon sequelae, unless anorexia or vomiting occurs. Potassium supplements may be given if hypokalemia is documented. However, these should be used cautiously if an ACEI and/or spironolactone (see Table 3-3 and p. 62) are also being administered to prevent hyperkalemia, especially if renal disease is present.

Spironolactone is thought to be useful for chronic therapy because of its aldosterone-antagonist, as well as potential diuretic, effects. Increased aldosterone production develops as a component of neurohormonal activation in heart failure, but ACEIs do not fully suppress this. Aldosterone is known to promote cardiovascular fibrosis and abnormal remodeling and as such contributes to the progression of cardiac disease. Therefore spironolactone is advocated as adjunctive therapy in combination with an ACEI, furosemide, and pimobendan/digoxin for chronic DCM therapy.

An ACEI should be used in the chronic treatment of DCM. Angiotensin-converting enzyme inhibition can attenuate progressive ventricular dilation and secondary mitral regurgitation. ACEIs have a positive effect on survival in both people and dogs with myocardial failure. These drugs minimize clinical signs and increase exercise tolerance. Enalapril or benazepril are used most extensively, but other ACEIs have similar effects.

The pure arteriolar dilator hydralazine can also improve cardiac output and exercise tolerance, as well as help reduce congestion; however, it can precipitate hypotension and reflex tachycardia, and it tends to exacerbate neurohormonal activation. Hydralazine can be used in combination with a nitrate in dogs that do not tolerate an ACEI. Hydralazine or amlodipine (see Table 3-3) could also be useful as adjunct therapy for dogs with refractory CHF, although arterial blood pressure should be carefully monitored in such animals. Any vasodilator must be used cautiously in dogs with a low cardiac reserve because of the increased potential for hypotension. Therapy is initiated at a low dose; if this is well-tolerated, the next dose is increased to a low maintenance level. The patient should be evaluated for several hours after each incremental dose, ideally by blood pressure measurement. Signs of worsening tachycardia, weakened pulses, or lethargy also can indicate the presence of hypotension. The jugular venous PO2 can be used to estimate directional changes in cardiac output; a venous PO<sub>2</sub> >30 mm Hg is desirable.

A number of other therapies may be useful in certain dogs with DCM, although additional studies are needed to define optimal recommendations. These include omega-3 fatty acids, L-carnitine (in dogs with low myocardial carnitine concentrations), taurine (in dogs with low plasma concentrations), long-term  $\beta$ -blocker therapy (e.g., carvedilol or metoprolol), and possibly others (see Chapter 3, p. 69). Several palliative surgical therapies for DCM have been described in dogs but are not widely used.

# Monitoring

Many dogs can be maintained fairly well for a variable time with chronic oral therapy. Owner education regarding the purpose, dosage, and adverse effects of each drug used is also important. Monitoring the dog's resting respiratory (and heart) rate at home helps assess how well the patient's CHF is controlled. Periodic reevaluation is important, but the time frame depends on the animal's status. Visits once or twice a week may be needed initially. Dogs with stable heart failure can be rechecked every 2 or 3 months. Serum electrolyte and creatinine (or BUN) concentrations, an ECG, pulmonary status, blood pressure, serum digoxin concentration, body weight, and other appropriate factors can be evaluated, and therapy adjusted as needed.

# **Prognosis**

The prognosis for dogs with DCM is generally guarded to poor. Historically, most dogs do not survive longer than 3 months after the clinical manifestations of CHF, although approximately 25% to 40% of affected dogs live longer than 6 months if initial response to therapy is good. The probability of survival for 2 years is estimated at 7.5% to 28%. However, the advent of newer therapies may change this bleak picture. Pleural effusion and possibly ascites and pulmonary edema have been identified as independent indicators of poorer prognosis.

Sudden death may occur even in the occult stage, before heart failure is apparent. Sudden death occurs in about 20% to 40% of affected Doberman Pinschers. Although ventricular tachyarrhythmias are thought to precipitate cardiac arrest most commonly, bradyarrhythmias may be involved in some dogs.

Doberman Pinschers with occult DCM often experience deterioration within 6 to 12 months. Dobermans in overt CHF when initially presented generally do not live long, with a reported median survival of less than 7 weeks. The prognosis is worse if AF is present in dogs with CHF. Most symptomatic dogs are between 5 and 10 years old at the time of death.

In each case, however, it is reasonable to assess the animal's response to initial treatment before pronouncing an unequivocally dismal prognosis. Early diagnosis may help prolong life; further cardiac evaluation is indicated for dogs with a history of reduced exercise tolerance, weakness, or syncope or in those in which an arrhythmia, murmur, or gallop sound is detected.

# ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

# CARDIOMYOPATHY IN BOXERS

Myocardial disease in Boxers has similar features to those of people with ARVC. Histologic changes in the myocardium are more extensive than those in dogs of other breeds with cardiomyopathy and include atrophy of myofibers, fibrosis, and fatty infiltration. Focal areas of myocytolysis, necrosis, hemorrhage, and mononuclear cell infiltration are also common.

Although clinical features vary, the prevalence of ventricular arrhythmias and syncope is high in Boxers with myocardial disease. A genetic basis is believed to exist given that the disease is more prevalent in some bloodlines. Three disease categories have been described. The first consists of dogs with ventricular tachyarrhythmia but without clinical signs. The second consists of dogs that have syncope or weakness associated with paroxysmal or sustained ventricular tachycardia, despite normal heart size and LV function. The third group comprises Boxers with poor myocardial function and CHF, as well as ventricular tachyarrhythmias. Dogs with mild echocardiographic changes and those with syncope or weakness may later develop poor LV function and CHF. There appears to be geographical variation in the prevalence of these clinical presentations; for example, tachyarrhythmias with normal LV function are typical in affected U.S. Boxers, whereas I.V dysfunction appears to be more common in parts of Europe.

## Clinical Findings

Signs may appear at any age, but the mean age is reportedly 8.5 years (range <1-15 years). The most consistent clinical finding is a cardiac arrhythmia. When CHF occurs, left-sided signs are more common than ascites or other signs of right-sided heart failure. Many Boxers also develop a mitral insufficiency murmur.

The radiographic findings are variable; many Boxers have no visible abnormalities. Those with congestive signs generally show evidence of cardiomegaly and pulmonary edema. Echocardiographic findings also vary. Many Boxers have normal cardiac size and function; others show chamber dilation with reduced fractional shortening.

The characteristic ECG finding is ventricular ectopy. VPCs occur singly, in pairs, in short runs, or as sustained ventricular tachycardia. Most ectopic ventricular complexes appear upright in leads II and aVF. Some Boxers have multiform VPCs. There usually is an underlying sinus rhythm. AF is less common. Supraventricular tachycardia, conduction abnormalities, and evidence of chamber enlargement also are sometimes seen on ECG.

Twenty-four-hour Holter monitoring is often used as a screening tool for Boxer ARVC. It also is recommended to evaluate the efficacy of antiarrhythmic drug therapy. Frequent VPCs and/or complex ventricular arrhythmias are characteristic findings in affected dogs. However, an absolute number of VPCs/24-hour period that might separate normal from abnormal dogs is not (and may never be) clear. An

arbitrary cut-off of >50 VPCs/24-hour period is often used to designate an abnormal frequency. However, there can be enormous variability in the number of VPCs between repeated Holter recordings in the same dog. Very frequent VPCs or episodes of ventricular tachycardia are thought to signal an increased risk for syncope and sudden death.

#### **Treatment**

Boxers with signs from tachyarrhythmias, but with normal heart size and LV function, are treated with antiarrhythmic drugs. Some asymptomatic dogs found to have ventricular tachycardia on Holter monitoring are also given an antiarrhythmic drug. The best regimen(s) and when to institute therapy are still not clear. Antiarrhythmic drug therapy that is apparently successful in reducing VPC number based on Holter recording may still not prevent sudden death. Sotalol, mexiletine with atenolol, amiodarone, or procainamide with atenolol have been advocated (see Chapter 4) because they might reduce the risk for sudden death from ventricular fibrillation, but further study is needed. Some dogs require treatment for persistent supraventricular tachyarrhythmias.

Therapy for CHF is similar to that described for dogs with idiopathic DCM. Myocardial carnitine deficiency has been documented in some Boxers with DCM and heart failure. Some of these dogs have responded to oral L-carnitine supplementation. Digoxin is used sparingly, if at all, when ventricular tachyarrhythmias are frequent.

# **Prognosis**

The prognosis for affected Boxers is guarded. Survival is often <6 months in those with CHF. Asymptomatic dogs may have a more optimistic future, but the likelihood of developing serious arrhythmias is high. Sudden death is common, presumably from VPCs leading to ventricular fibrillation. The ventricular tachyarrhythmias may be refractory to drug therapy. Furthermore, even if most arrhythmias are suppressed, an increased survival is not assured.

# ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY IN NONBOXER DOGS

A form of cardiomyopathy that mainly affects the right ventricle has been observed rarely in dogs. It appears similar to ARVC described in people and cats (see p. 154). Pathologic changes are characterized by widespread fibrous and fatty tissue replacement in the RV myocardium. In certain geographical areas, trypanosomiasis is a possible differential diagnosis. Clinical manifestations are largely related to right-sided CHF and severe ventricular tachyarrhythmias. Marked right heart dilation is typical. Sudden death is a common outcome in people with ARVC.

# SECONDARY MYOCARDIAL DISEASE

Poor myocardial function may result from a variety of identifiable insults and nutritional deficiencies. Myocardial infec-

tions (see p. 137), inflammation, trauma (see p. 139), ischemia, neoplastic infiltrations, and metabolic abnormalities can impair normal contractile function. Hyperthermia, irradiation, electric shock, and other insults can also damage the myocardium. Some substances are known cardiac toxins.

# MYOCARDIAL TOXINS Doxorubicin

The antineoplastic drug doxorubicin induces both acute and chronic cardiotoxicity. Histamine, secondary catecholamine release, and free-radical production appear to be involved in the pathogenesis of myocardial damage, which leads to decreased cardiac output, arrhythmias, and degeneration of myocytes. Doxorubicin-induced cardiotoxicity is directly related to the peak serum concentration of the drug; administering the drug diluted (0.5 mg/ml) over 20 to 40 minutes minimizes the risk of developing cardiotoxicity. Progressive myocardial damage and fibrosis have developed in association with cumulative doses of >160 mg/m<sup>2</sup> and sometimes as low as 100 mg/m<sup>2</sup>. In dogs that have normal pretreatment cardiac function, clinical cardiotoxicity is uncommon until the cumulative dose exceeds 240 mg/m<sup>2</sup>. It is difficult to predict whether and when clinical cardiotoxicity will occur. Increases in circulating cardiac troponin concentrations can be seen, but more work is needed to clarify the utility of this in monitoring dogs for doxorubicin-induced myocardial injury.

Cardiac conduction defects (infranodal AV block and bundle branch block) as well as ventricular and supraventricular tachyarrhythmias can develop in affected dogs. ECG changes do not necessarily precede clinical heart failure. Dogs with underlying cardiac abnormalities and those of breeds with a higher prevalence of idiopathic DCM are thought to be at greater risk for doxorubicin-induced cardiotoxicity. Recently, carvedilol has been shown to minimize or prevent the development of doxorubicin-induced cardiotoxicity in humans; we have had similar anecdotal experiences in dogs. Clinical features of this cardiomyopathy are similar to those of idiopathic DCM.

#### **Other Toxins**

Ethyl alcohol, especially if given intravenously for the treatment of ethylene glycol intoxication, can cause severe myocardial depression and death; slow administration of a diluted (20% or less) solution is advised. Other cardiac toxins include plant toxins (e.g., *Taxus*, foxglove, black locust, buttercups, lily-of-the-valley, gossypol), cocaine, anesthetic drugs, cobalt, catecholamines, and ionophores such as monensin.

# METABOLIC AND NUTRITIONAL DEFICIENCY L-carnitine

L-carnitine is an essential component of the mitochondrial membrane transport system for fatty acids, which are the heart's most important energy source. It also transports potentially toxic metabolites out of the mitochondria in the form of carnitine esters. L-carnitine—linked defects in myocardial metabolism have been found in some dogs with DCM. Rather than simple L-carnitine deficiency, one or more underlying genetic or acquired metabolic defects are suspected. There may be an association between DCM and carnitine deficiency in some families of Boxers, Doberman Pinschers, Great Danes, Irish Wolfhounds, Newfoundlands, and Cocker Spaniels. L-carnitine is mainly present in foods of animal origin. DCM has developed in some dogs fed strict vegetarian diets.

Plasma carnitine concentration is not a sensitive indicator of myocardial carnitine deficiency. Most dogs with myocardial carnitine deficiency, diagnosed via endomyocardial biopsy, have had normal or high plasma carnitine concentrations. Furthermore, the response to oral carnitine supplementation is inconsistent. Subjective improvement may occur, but few dogs have echocardiographic evidence of improved function. Dogs that do respond show clinical improvement within the first month of supplementation; there may be some degree of improvement in echo parameters after 2 to 3 months. L-carnitine supplementation does not suppress preexisting arrhythmias or prevent sudden death. See p. 69 for supplementation guidelines.

#### **Taurine**

Although most dogs with DCM are not taurine deficient, low plasma taurine concentration is found in some. Low taurine, and sometimes carnitine, concentrations occur in Cocker Spaniels with DCM. Oral supplementation of these amino acids can improve LV size and function as well as reduce the need for heart failure medications in this breed. Low plasma taurine concentrations have also been found in some Golden Retrievers, Labrador Retrievers, Saint Bernards, Dalmatians, and other dogs with DCM. A normally adequate taurine content is found in the diets of some such cases, although others have been fed low-protein or vegetarian diets. The role of taurine supplementation is unclear. Although taurinedeficient dogs may show some echocardiographic improvement after supplementation, there is questionable effect on survival time. Nevertheless, measurement of plasma taurine or a trial of supplemental taurine for at least 4 months may be useful, especially in an atypical breed affected with DCM. (See p. 69 for supplementation guidelines.) Plasma taurine concentrations <25 (to 40) nmol/ml and blood taurine concentrations <200 (or 150) nmol/ml are generally considered deficient. Specific collection and submission guidelines should be obtained from the laboratory used.

#### Other Factors

Myocardial injury induced by free radicals may play a role in a number of diseases. Evidence for increased oxidative stress has been found in dogs with CHF and myocardial failure, but the clinical ramifications of this are unclear. Diseases such as hypothyroidism, pheochromocytoma, and diabetes mellitus have been associated with reduced myocardial function, but clinical heart failure is unusual in dogs secondary to these conditions alone. Excessive sympathetic stimulation stemming from brain or spinal cord injury results in myocardial hemorrhage, necrosis, and arrhythmias (brain-heart syndrome). Muscular dystrophy of the fasciohumoral type (reported in English Springer Spaniels) may result in atrial standstill and heart failure. Canine X-linked (Duchenne's) muscular dystrophy in Golden Retrievers and other breeds also has been associated with myocardial fibrosis and mineralization. Rarely, nonneoplastic (e.g., glycogen storage disease) and neoplastic (metastatic and primary) infiltrates interfere with normal myocardial function. Immunologic mechanisms may also play an important role in the pathogenesis of myocardial dysfunction in some dogs with myocarditis.

# ISCHEMIC MYOCARDIAL DISEASE

Acute myocardial infarction resulting from coronary embolization is uncommon. An underlying disease associated with increased risk for thromboembolism, such as bacterial endocarditis, neoplasia, severe renal disease, immune-mediated hemolytic anemia, acute pancreatitis, disseminated intravascular coagulopathy, and/or corticosteroid use, underlies most cases. Sporadic reports of myocardial infarction are associated with congenital ventricular outflow obstruction, patent ductus arteriosus, hypertrophic cardiomyopathy, and mitral insufficiency. Atherosclerosis of the major coronary arteries, which can accompany severe hypothyroidism in dogs, rarely leads to acute myocardial infarction. Clinical signs of acute major coronary artery obstruction are likely to include arrhythmias, pulmonary edema, marked ST segment change on ECG, and evidence of regional or global myocardial contractile dysfunction on echocardiogram. High circulating cardiac troponin concentrations and possibly creatine kinase activity occur after myocardial injury and necrosis.

Disease of small coronary vessels is recognized as well. Non-atherosclerotic narrowing of small coronary arteries could be more clinically important than previously assumed. Hyalinization of small coronary vessels and intramural myocardial infarctions have been described in dogs with chronic degenerative AV valve disease, but they can occur in older dogs without valve disease as well. Fibromuscular arteriosclerosis of small coronary vessels is also described. These changes in the walls of the small coronary arteries cause luminal narrowing and can impair resting coronary blood flow as well as vasodilatory responses. Small myocardial infarctions and secondary fibrosis lead to reduced myocardial function. Various arrhythmias can occur. Eventual CHF is a cause of death in many cases with intramural coronary arteriosclerosis. Sudden death is a less common sequela. Larger breeds of dog may be predisposed, although Cocker Spaniels and Cavalier King Charles Spaniels appear to be commonly affected smaller breeds.

# TACHYCARDIA-INDUCED CARDIOMYOPATHY

The term tachycardia induced cardiomyopathy (TICM) refers to the progressive myocardial dysfunction, activation of neurohormonal compensatory mechanisms, and CHF that result from rapid, incessant tachycardias. The myocardial failure may be reversible if the heart rate can be normalized in time. TICM has been described in several dogs with AV nodal reciprocating tachycardias associated with accessory conduction pathways that bypass the AV node (e.g., Wolff-Parkinson-White; see p. 27). Rapid artificial pacing (e.g., >200 beats/min) is a common model for inducing experimental myocardial failure that simulates DCM.

#### HYPERTROPHIC CARDIOMYOPATHY

In contrast to cats, hypertrophic cardiomyopathy (HCM) is quite uncommon in dogs. A genetic basis is suspected, although the cause is unknown. It is possible that several disease processes lead to similar ventricular changes. The pathophysiology is similar to that of HCM in cats (see Chapter 8). Abnormal, excessive myocardial hypertrophy increases ventricular stiffness and leads to diastolic dysfunction. The IV hypertrophy is usually symmetric, but regional variation in wall or septal thickness can occur. Compromised coronary perfusion is likely with severe ventricular hypertrophy. This leads to myocardial ischemia, which exacerbates arrhythmias, delays ventricular relaxation, and further impairs filling. High LV filling pressure predisposes to pulmonary venous congestion and edema. Besides diastolic dysfunction, systolic dynamic LV outflow obstruction occurs in some dogs. Malposition of the mitral apparatus may contribute to systolic anterior mitral valve motion and IV outflow obstruction as well as to mitral regurgitation. In some dogs asymmetric septal hypertrophy also contributes to outflow obstruction. IV outflow obstruction increases ventricular wall stress and myocardial oxygen requirement while also impairing coronary blood flow. Heart rate elevations magnify these abnormalities.

#### **Clinical Features**

HCM is most commonly diagnosed in young to middle-age large-breed dogs, although there is a wide age distribution. Various breeds are affected. There may be a higher prevalence of HCM in males. Clinical signs of CHF, episodic weakness, and/or syncope occur in some dogs. Sudden death is the only sign in some cases. Ventricular arrhythmias secondary to myocardial ischemia are presumed to cause the low-output signs and sudden death. A systolic murmur, related to either LV outflow obstruction or mitral insufficiency, may be heard on auscultation. The systolic ejection murmur of ventricular outflow obstruction becomes louder when ventricular contractility is increased (e.g., with exercise or excitement) or when afterload is reduced (e.g., from vasodilator use). An S<sub>4</sub> gallop sound is heard in some affected dogs.

# **Diagnosis**

Echocardiography is the best diagnostic tool for HCM. An abnormally thick left ventricle, with or without narrowing of the LV outflow tract area or asymmetrical septal hypertrophy, and LA enlargement are characteristic findings. Mitral regurgitation may be evident on Doppler studies. Systolic anterior motion of the mitral valve may result from

dynamic outflow obstruction causes. Partial systolic aortic valve closure may be seen as well. Other causes of LV hypertrophy include congenital subaortic stenosis, hypertensive renal disease, thyrotoxicosis, and pheochromocytoma. Thoracic radiographs may indicate LA and LV enlargement, with or without pulmonary congestion or edema. Some cases appear radiographically normal. ECG findings may include ventricular tachyarrhythmias and conduction abnormalities, such as complete heart block, first-degree AV block, and fascicular blocks. Criteria for LV enlargement are variably present.

#### **Treatment**

The general goals of HCM treatment are to enhance myocardial relaxation and ventricular filling, control pulmonary edema, and suppress arrhythmias. A β-blocker (see p. 89) or Ca++-channel blocker (see p. 91) may lower heart rate, prolong ventricular filling time, reduce ventricular contractility, and minimize myocardial oxygen requirement. βblockers can also reduce dynamic LV outflow obstruction and may suppress arrhythmias induced by heightened sympathetic activity, whereas Ca't-blockers may facilitate myocardial relaxation. Diltiazem has a lesser inotropic effect and would be less useful against dynamic outflow obstruction, especially in view of its vasodilating effect. Because β- and Ca++-channel blockers can worsen AV conduction abnormalities, they may be relatively contraindicated in certain animals. A diuretic and ACEI are indicated if congestive signs are present. Digoxin should not be used because it may increase myocardial oxygen requirements, worsen outflow obstruction, and predispose to the development of ventricular arrhythmias. Exercise restriction is advised in dogs with HCM.

#### **MYOCARDITIS**

A wide variety of agents can affect the myocardium, although disease manifestations in other organ systems may overshadow the cardiac involvement. The heart can be injured by direct invasion of the infective agent, by toxins it elaborates, or by the host's immune response. Non-infective causes of myocarditis include cardiotoxic drugs and drug hypersensitivity reactions. Myocarditis can cause persistent cardiac arrhythmias and progressively impair myocardial function.

# INFECTIVE MYOCARDITIS

# Etiology and Pathophysiology Viral Myocarditis

Lymphocytic myocarditis has been associated with acute viral infections in experimental animals and in people. Cardiotropic viruses can play an important role in the pathogenesis of myocarditis and subsequent cardiomyopathy in several species, but this is not recognized commonly in dogs. The host animal's immune responses to viral and nonviral antigens contribute to myocardial inflammation and damage.

A syndrome of parvoviral myocarditis was well-known in the late 1970s and early 1980s. It is characterized by a peracute necrotizing myocarditis and sudden death (with or without signs of acute respiratory distress) in apparently healthy puppies about 4 to 8 weeks old. Cardiac dilation with pale streaks in the myocardium, gross evidence of congestive failure, large basophilic or amorphophilic intranuclear inclusion bodies, myocyte degeneration, and focal mononuclear cell infiltrates are typical necropsy findings. This syndrome is uncommon now, probably as a result of maternal antibody production in response to virus exposure and vaccination. Parvovirus may cause a form of DCM in young dogs that survive neonatal infection; viral genetic material has been identified in some canine ventricular myocardial samples in the absence of classic intranuclear inclusion bodies.

Canine distemper virus may cause myocarditis in young puppies, but multisystemic signs usually predominate. Histologic changes in the myocardium are mild compared with those in the classic form of parvovirus myocarditis. Experimental herpesvirus infection of pups during gestation also causes necrotizing myocarditis with intranuclear inclusion bodies leading to fetal or perinatal death.

# **Bacterial Myocarditis**

Bacteremia and bacterial endocarditis or pericarditis can cause focal or multifocal suppurative myocardial inflammation or abscess formation. Localized infections elsewhere in the body may be the source of the organisms. Clinical signs include malaise; weight loss; and, inconsistently, fever. Arrhythmias and cardiac conduction abnormalities are common, but murmurs are rare unless concurrent valvular endocarditis or another underlying cardiac defect is present. Serial bacterial (or fungal) blood cultures, serology, or PCR may allow identification of the organism. *Bartonella vinsonii* subspecies have been associated with cardiac arrhythmias, myocarditis, endocarditis, and sudden death.

# **Lyme Carditis**

Lyme disease is more prevalent in certain geographic areas, especially the northeastern, western coastal, and north central United States, as well as in Japan and Europe, among other areas. The spirochete Borrelia burgdorferi (or related species) is transmitted to dogs by ticks (especially Ixodes genus) and possibly other biting insects. Third-degree (complete) and high-grade second-degree AV block have been identified in dogs with Lyme disease. Syncope, CHF, reduced myocardial contractility, and ventricular arrhythmias also are reported in affected dogs. Pathologic findings of Lyme myocarditis include infiltrates of plasma cells, macrophages, neutrophils, and lymphocytes, with areas of myocardial necrosis. These are similar to findings in human Lyme carditis. A presumptive diagnosis is made on the basis of the finding of positive (or increasing) serum titers or a positive SNAP test and concurrent signs of myocarditis, with or without other systemic signs. The findings from endomyocardial biopsy, if available, may be helpful in confirming the diagnosis. Treatment with an appropriate antibiotic should be instituted pending diagnostic test results. Cardiac drugs are used as needed. Resolution of AV conduction block may not occur in dogs despite appropriate antimicrobial therapy.

# **Protozoal Myocarditis**

Trypanosoma cruzi, Toxoplasma gondii, Neosporum caninum, Babesia canis, and Hepatozoon canis are known to affect the myocardium. Trypanosomiasis (Chagas' disease) has occurred mainly in young dogs in Texas, Louisiana, Oklahoma, Virginia, and other southern states in the United States. The possibility for human infection should be recognized; this is an important cause of human myocarditis and subsequent cardiomyopathy in Central and South America. The organism is transmitted by bloodsucking insects of the family Reduviidae and is enzootic in wild animals of the region. Amastigotes of T. cruzi cause myocarditis with a mononuclear cell infiltrate and disruption and necrosis of myocardial fibers. Acute, latent, and chronic phases of Chagas' myocarditis have been described. Lethargy, depression, and other systemic signs, as well as various tachyarrhythmias, AV conduction defects, and sudden death, are seen in dogs with acute trypanosomiasis. Clinical signs are sometimes subtle. The disease is diagnosed in the acute stage by finding trypomastigotes in thick peripheral blood smears; the organism can be isolated in cell culture or by inoculation into mice. Animals that survive the acute phase enter a latent phase of variable duration. During this phase the parasitemia is resolved, and antibodies develop against the organism as well as cardiac antigens. Chronic Chagas' disease is characterized by progressive right-sided or generalized cardiomegaly and various arrhythmias. Ventricular tachvarrhythmias are most common, but supraventricular tachyarrhythmias may occur. Right bundle branch block and AV conduction disturbances are also reported. Ventricular dilation and reduced myocardial function are usually evident echocardiographically. Clinical signs of biventricular failure are common. Antemortem diagnosis in chronic cases may be possible through serologic testing. Therapy in the acute stage is aimed at eliminating the organism and minimizing myocardial inflammation; several treatments have been tried with variable success. The therapy for chronic Chagas' disease is aimed at supporting myocardial function, controlling congestive signs, and suppressing arrhythmias.

Toxoplasmosis and neosporiosis can cause clinical myocarditis in conjunction with generalized systemic infection, especially in the immunocompromised animal. The organism becomes encysted in the heart and various other body tissues after the initial infection. With rupture of these cysts, expelled bradyzoites induce hypersensitivity reactions and tissue necrosis. Other systemic signs often overshadow signs of myocarditis. Immunosuppressed dogs with chronic toxoplasmosis (or neosporiosis) may be prone to active disease, including clinically relevant myocarditis, pneumonia, chorioretinitis, and encephalitis. Antiprotozoal therapy may be successful. Babesiosis can be associated with cardiac lesions in dogs, including myocardial hemorrhage, inflammation, and necrosis. Pericardial effusion and variable ECG changes are also noted in some cases. A correlation between plasma cardiac troponin I (cTnI) concentration and clinical severity, survival, and cardiac histopathologic findings was shown in dogs with babesiosis.

*H. canis* may involve the myocardium during part of its life cycle; this was found in dogs along the Texas coast. Infection occurs as a result of ingesting the organism's definitive host, the brown dog tick (*Rhipicephalus sanguineus*). Clinical signs include stiffness, anorexia, fever, neutrophilia, and periosteal new bone reaction.

#### Other Causes

Rarely, fungi (Aspergillus, Cryptococcus, Coccidioides, Histoplasma, Paecilomyces), rickettsiae (Rickettsia rickettsii, Ehrlichia canis, Bartonella elizabethae), algaelike organisms (Prototheca sp.), and nematode larval migration (Toxocara sp.) cause myocarditis. Affected animals are usually immunosuppressed and have systemic signs of disease. Rocky Mountain spotted fever (R. rickettsii) occasionally causes fatal ventricular arrhythmias, along with necrotizing vasculitis, myocardial thrombosis, and ischemia. Angiostrongylus vasorum infection in association with immune-mediated thrombocytopenia has rarely caused myocarditis, thrombosing arteritis, and sudden death.

# **Clinical Findings and Diagnosis**

Unexplained onset of arrhythmias or heart failure after a recent episode of infective disease or drug exposure is the classic clinical presentation of acute myocarditis. However, definitive diagnosis is difficult because clinical and clinicopathologic findings are usually nonspecific and inconsistent. A database including complete blood count, serum biochemical profile with creatine kinase activity, cardiac troponin concentration, thoracic and abdominal radiographs, and urinalysis are usually obtained. ECG changes could include an ST segment shift, T-wave or QRS voltage changes, AV conduction abnormalities, and various arrhythmias. Echocardiographic signs of poor regional or global wall motion, altered myocardial echogenicity, or pericardial effusion may be evident. In dogs with persistent fever, serial bacterial (or fungal) blood cultures may be useful. Serologic screening for known infective causes may or may not be helpful. Histologic criteria for a diagnosis of myocarditis include inflammatory infiltrates with myocyte degeneration and necrosis. Endomyocardial biopsy specimens are currently the only means of obtaining a definitive antemortem diagnosis, but if the lesions are focal, the findings may not be diagnostic.

## **Treatment**

Unless a specific etiology can be identified and treated, therapy for suspected myocarditis is largely supportive. Strict rest, antiarrhythmic drugs (see Chapter 4), therapy to support myocardial function and manage CHF signs (see Chapter 3), and other support are used as needed. Corticosteroids are

not proven to be clinically beneficial in dogs with myocarditis, and considering the possible infective cause, they are not recommended as nonspecific therapy. Exceptions would be confirmed immune-mediated disease, drug-related or eosinophilic myocarditis, or confirmed nonresolving myocarditis.

#### **NON-INFECTIVE MYOCARDITIS**

Myocardial inflammation can result from the effects of drugs, toxins, or immunologic responses. Although there is little clinical documentation for many of these in dogs, a large number of potential causes have been identified in people. Besides the well-known toxic effects of doxorubicin and catecholamines, other potential causes of non-infective myocarditis include heavy metals (e.g., arsenic, lead, mercury), antineoplastic drugs (cyclophosphamide, 5-fluorouracil, interleukin-2, alpha-interferon), other drugs (e.g., thyroid hormone, cocaine, amphetamines, lithium), and toxins (wasp or scorpion stings, snake venom, spider bites). Immunemediated diseases and pheochromocytoma can cause myocarditis as well. Hypersensitivity reactions to many antiinfective agents and other drugs have also been identified as causes of myocarditis in people. Drug-related myocarditis is usually characterized by eosinophilic as well as lymphocytic infiltrates.

#### TRAUMATIC MYOCARDITIS

Nonpenetrating or blunt trauma to the chest and heart is more common than penetrating wounds. Cardiac arrhythmias are frequently observed after such trauma, especially in dogs. Cardiac damage can result from impact against the chest wall, compression, or acceleration-deceleration forces. Other possible mechanisms of myocardial injury and arrhythmogenesis include an autonomic imbalance, ischemia, reperfusion injury, and electrolyte and acid-base disturbances. Thoracic radiographs, serum biochemistries, circulating cardiac troponin concentrations, ECG, and echocardiography are recommended in the assessment of these cases. Echocardiography can define preexisting heart disease, global myocardial function, and unexpected cardiovascular findings, but it may not identify small areas of myocardial injury.

Arrhythmias usually appear within 24 to 48 hours after trauma, although they can be missed on intermittent ECG recordings. VPCs, ventricular tachycardia, and accelerated idioventricular rhythms (with rates of 60 to 100 beats/min or slightly faster) are more common than supraventricular tachyarrhythmias or bradyarrhythmias in these patients. Accelerated idioventricular rhythms usually are manifested only when the sinus rate slows or pauses; they are benign in most dogs with normal underlying heart function and disappear with time (generally within a week or so). Antiarrhythmic therapy for accelerated idioventricular rhythm in this setting is usually unnecessary. The patient as well as the ECG should be monitored closely. More serious arrhythmias (e.g., faster rate) or hemodynamic deterioration may require antiarrhythmic therapy (see Chapter 4).

Traumatic avulsion of AV valve papillary muscles, septal perforation, and rupture of the heart or pericardium have also been reported. Traumatic papillary muscle avulsion causes acute volume overload with acute onset of CHF. Signs of low-output failure and shock, as well as arrhythmias, can develop rapidly after cardiac trauma.

Myocarditis

Myocardial disease in cats encompasses a diverse collection of idiopathic and secondary processes affecting the myocardium. The spectrum of anatomic and pathophysiologic features is wide. Disease characterized by myocardial hypertrophy is most common, although features of multiple pathophysiologic categories co-exist in some cats. Restrictive pathophysiology develops often. Classic dilated cardiomyopathy is now uncommon in cats; its features are similar to those of dilated cardiomyopathy in dogs (see Chapter 7). Myocardial disease in some cats does not fit neatly into the categories of hypertrophic, dilated, or restrictive cardiomyopathy and therefore is considered indeterminate or unclassified cardiomyopathy. Arterial thromboembolism is a major complication in cats with myocardial disease.

# HYPERTROPHIC CARDIOMYOPATHY

# **Etiology**

The cause of primary or idiopathic hypertrophic cardiomyopathy (HCM) in cats is unknown, but a heritable abnormality is likely in many cases. Disease prevalence appears to be high in several breeds, such as the Maine Coon, Persian, Ragdoll, and American Shorthair. There are also reports of HCM in litter mates and other closely related domestic shorthair cats. An autosomal dominant inheritance pattern has been found in some breeds. In human familial HCM, many different gene mutations are known to exist. Although several common human gene mutations have not yet similarly been found in feline HCM, others may be in the future. Reduced myomesin (a sarcomeric protein) occurs in some affected Maine Coon cats. The same researchers (Meurs et al. 2005) also found a mutation in cardiac myosin-binding protein C in this breed. Another mutation has been identified in Ragdoll cats; testing for these mutations is currently available (contact www.vetmed.wsu.edu/deptsVCGL/ felineTests.aspx).

In addition to mutations of genes that encode for myocardial contractile or regulatory proteins, possible causes of the disease include an increased myocardial sensitivity to or excessive production of catecholamines; an abnormal hypertrophic response to myocardial ischemia, fibrosis, or trophic factors; a primary collagen abnormality; and abnormalities of the myocardial calcium-handling process. Myocardial hypertrophy with foci of mineralization occurs in cats with hypertrophic feline muscular dystrophy, an Xlinked recessive dystrophin deficiency similar to Duchenne muscular dystrophy in people; however, congestive heart failure (CHF) is uncommon in these cats. Some cats with HCM have high serum growth hormone concentrations. It is not clear whether viral myocarditis has a role in the pathogenesis of feline cardiomyopathy. One study of myocardial samples from cats with HCM evaluated by polymerase chain reaction (PCR) showed evidence of panleukopenia virus DNA in approximately one third of the cats with myocarditis but in none of the healthy control cats (Meurs, 2000).

# **Pathophysiology**

Thickening of the left ventricular (LV) wall and/or interventricular septum is characteristic, but the extent and distribution of hypertrophy in cats with HCM are variable. Many cats have symmetric hypertrophy, but some have asymmetric septal thickening, and a few have hypertrophy limited to the free wall or papillary muscles. The LV lumen usually appears small. Focal or diffuse areas of fibrosis occur within the endocardium, conduction system, or myocardium; narrowing of small intramural coronary arteries may also be noted. Areas of myocardial infarction as well as myocardial fiber disarray may be present.

Myocardial hypertrophy and the accompanying changes increase ventricular wall stiffness. Additionally, early active myocardial relaxation may be slow and incomplete, especially in the presence of myocardial ischemia. This further reduces ventricular distensibility and promotes diastolic dysfunction. This ventricular stiffness impairs LV filling and increases diastolic pressure. LV volume remains normal or decreased. Reduced ventricular volume results in a lower stroke volume, which may contribute to neurohormonal activation. Higher heart rates further interfere with LV filling, promote myocardial ischemia, and contribute to pulmonary venous congestion and edema by shortening the diastolic filling period. Contractility, or systolic function, is usually normal in affected cats. However, some cats experience progression to ventricular systolic failure and dilation.

Progressively higher LV filling pressures lead to increased left atrial (LA) and pulmonary venous pressures. Progressive LA dilation as well as pulmonary congestion and edema can result. The degree of LA enlargement varies from mild to massive. A thrombus is sometimes found within the LV or attached to a ventricular wall, although it is more commonly located in the LA. Arterial thromboembolism is a major complication of HCM as well as other forms of cardiomy-opathy in cats (see Chapter 12). Mitral regurgitation develops in some affected cats. Changes in LV geometry, papillary muscle structure, or the systolic movement of the mitral valve (systolic anterior motion [SAM]) may prevent normal valve closure. Valve insufficiency exacerbates the increased LA size and pressure.

Systolic dynamic LV outflow obstruction occurs in some cats. This is also known as hypertrophic obstructive cardiomyopathy or functional subaortic stenosis. Excessive asymmetric hypertrophy of the basilar interventricular septum may be evident on echocardiograms or at necropsy. Systolic outflow obstruction increases LV pressure, wall stress, and myocardial oxygen demand and promotes myocardial ischemia. Mitral regurgitation is exacerbated by the tendency of hemodynamic forces to pull the anterior mitral leaflet toward the interventricular septum during ejection (SAM, see Figure 8-3). Increased LV outflow turbulence commonly causes an ejection murmur of variable intensity in these cats.

Several factors probably contribute to the development of myocardial ischemia in cats with HCM. These include narrowing of intramural coronary arteries, increased LV filling pressure, decreased coronary artery perfusion pressure, and insufficient myocardial capillary density for the degree of hypertrophy. Tachycardia contributes to ischemia by increasing myocardial O<sub>2</sub> requirements while reducing diastolic coronary perfusion time. Ischemia impairs early, active ventricular relaxation, which further increases ventricular filling pressure, and over time leads to myocardial fibrosis. Ischemia can provoke arrhythmias and possibly thoracic pain.

Atrial fibrillation (AF) and other tachyarrhythmias further impair diastolic filling and exacerbate venous congestion; the loss of the atrial "kick" and the rapid heart rate associated with AF are especially detrimental. Ventricular tachycardia or other arrhythmias may lead to syncope or sudden death.

Pulmonary venous congestion and edema result from increasing LA pressure. Increased pulmonary venous and capillary pressures are thought to cause pulmonary vasoconstriction; increased pulmonary arterial pressure and secondary right-sided CHF signs may occur. Eventually, refractory biventricular failure with profuse pleural effusion develops in some cats with HCM. The effusion is usually a modified transudate, although it can be (or become) chylous.

#### **Clinical Features**

HCM may be most common in middle-age male cats, but clinical signs can occur at any age. Cats with milder disease may be asymptomatic for years. Symptomatic cats are most often presented for respiratory signs of variable severity or acute signs of thromboembolism (see p. 195). Respiratory signs include tachypnea; panting associated with activity; dyspnea; and, only rarely, coughing (which can be misinterpreted as vomiting). Disease onset may seem acute in sedentary cats, even though pathologic changes have developed gradually. Occasionally, lethargy or anorexia is the only evidence of disease. Some cats have syncope or sudden death in the absence of other signs. Stresses such as anesthesia, surgery, fluid administration, systemic illnesses (e.g., fever or anemia), or boarding can precipitate CHF in an otherwise compensated cat. Asymptomatic disease is discovered in some cats when a murmur or gallop sound is heard during routine auscultation.

Systolic murmurs compatible with mitral regurgitation or LV outflow tract obstruction are common. Some cats do not have an audible murmur, even those with marked ventricular hypertrophy. A diastolic gallop sound (usually S<sub>4</sub>) may be heard, especially if heart failure is evident or imminent. Cardiac arrhythmias are relatively common. Femoral pulses are usually strong, unless distal aortic thromboembolism has occurred. The precordial impulse often feels vigorous. Prominent lung sounds, pulmonary crackles, and sometimes cyanosis accompany severe pulmonary edema. Pulmonary crackles are not always heard with edema in cats. Pleural effusion usually attenuates ventral pulmonary sounds. The physical examination may be normal in subclinical cases.

# Diagnosis

# **RADIOGRAPHY**

Radiographic features of HCM include a prominent left atrium and variable LV enlargement (Fig. 8-1). The classic valentine-shaped appearance of the heart on dorsoventral or ventrodorsal views is not always present, although usually the point of the left ventricular apex is maintained. The cardiac silhouette appears normal in most cats with mild HCM. Enlarged and tortuous pulmonary veins may be noted in cats with chronically high LA and pulmonary venous pressure. Left-sided CHF produces variable degrees of patchy interstitial or alveolar pulmonary edema infiltrates. The radiographic distribution of pulmonary edema is variable; a diffuse or focal distribution throughout the lung fields is common, in contrast to the characteristic perihilar distribution of cardiogenic pulmonary edema seen in dogs. Pleural effusion is common in cats with advanced or biventricular CHF.

#### **ELECTROCARDIOGRAPHY**

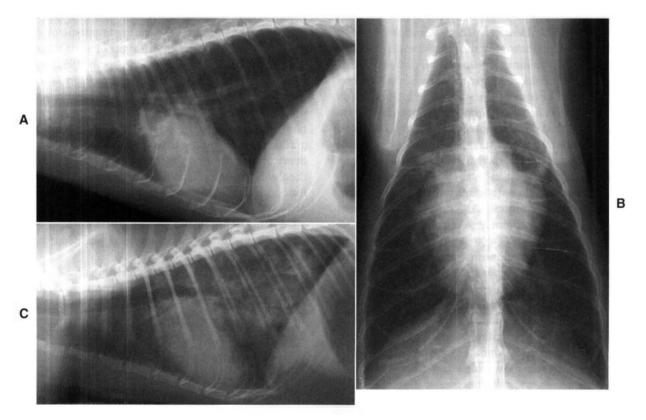

Many (up to 70%) cats with HCM have electrocardiogram (ECG) abnormalities. These include criteria for LA or LV enlargement, ventricular and/or (less often) supraventricular tachyarrhythmias, and a left anterior fascicular block pattern

(Fig. 8-2). Atrioventricular (AV) conduction delay, complete AV block, or sinus bradycardia is occasionally found.

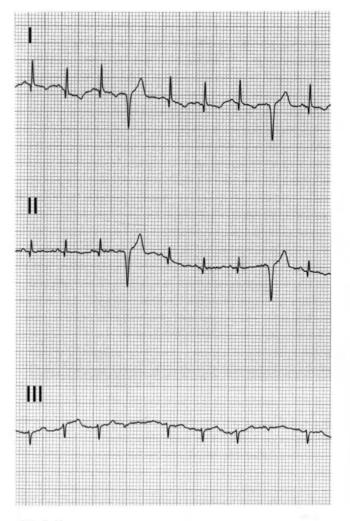

#### **ECHOCARDIOGRAPHY**

Echocardiography is the best means of diagnosis and differentiation of HCM from other disorders. The extent of hypertrophy and its distribution within the ventricular wall, septum, and papillary muscles is shown by two-dimensional and M-mode echo studies. Doppler techniques can demonstrate LV diastolic or systolic abnormalities.

Widespread myocardial thickening is common, and the hypertrophy is often asymmetrically distributed among various LV wall, septal, and papillary muscle locations. Focal areas of hypertrophy also occur. Use of two-dimensional-guided M-mode helps ensure proper beam position. Standard M-mode views and measurements are obtained, but thickened areas outside these standard positions should also be measured (Fig. 8-3). The diagnosis of early disease may be questionable in cats with mild or only focal thickening. Falsely increased thickness measurements (pseudohypertrophy) can occur with dehydration and sometimes tachycardia. Spurious diastolic thickness measurements also arise when the beam does not transect the wall/septum perpendicularly and when the measurement is not taken at the end of diastole, as can happen without simultaneous ECG record-

Radiographic examples of feline hypertrophic cardiomyopathy. Lateral (A) and dorsoventral (B) views showing atrial and mild ventricular enlargement in a male Domestic Shorthair cat. Lateral (C) view of a cat with hypertrophic cardiomyopathy and marked pulmonary edema.

# FIG 8-2 Electrocardiogram from a cat with hypertrophic cardiomyopathy showing occasional ventricular premature complexes and a left axis deviation. Leads I, II, III, at 25 mm/sec.

1 cm = 1 mV.

ing or when using two-dimensional imaging of insufficient frame rate. A (properly obtained) diastolic LV wall or septal thickness >5.5 mm is considered abnormal. Cats with severe HCM have diastolic LV wall or septal thicknesses of 8 mm or more, although the degree of hypertrophy is not necessarily correlated with the severity of clinical signs. Doppler-derived estimates of diastolic function, such as isovolumic relaxation time, and mitral inflow and pulmonary venous velocity patterns, as well as Doppler tissue imaging techniques are being employed more often to define disease characteristics.

Papillary muscle hypertrophy can be marked, and systolic LV cavity obliteration is observed in some cats. Increased echogenicity (brightness) of papillary muscles and subendocardial areas is thought to be a marker for chronic myocardial ischemia with resulting fibrosis. LV fractional shortening (FS) is generally normal to increased. However, some cats have mild to moderate LV dilation and reduced contractility (FS ~ 23%-29%; normal FS is 35%-65%). Right ventricular

enlargement and pericardial or pleural effusion are occasionally detected.

Cats with dynamic LV outflow tract obstruction also often have SAM of the mitral valve (Fig. 8-4) or premature closure of the aortic valve leaflets on M-mode scans. Doppler modalities can demonstrate mitral regurgitation and LV outflow turbulence (Fig. 8-5), although optimal alignment with the maximal-velocity outflow jet is often difficult and it is easy to underestimate the systolic gradient.

LA enlargement may be mild to marked. Spontaneous contrast (swirling, smoky echos) is visible within the enlarged LA of some cats. This is thought to result from blood stasis with cellular aggregations and to be a harbinger of thromboembolism. A thrombus is occasionally visualized within the left atrium, usually in the auricle (Fig. 8-6).

Other causes of myocardial hypertrophy (see p. 149) should be excluded before a diagnosis of idiopathic HCM is made. Myocardial thickening can also result from infiltrative disease. Variation in myocardial echogenicity or wall irregularities may be noted in such cases. Excess moderator bands appear as bright, linear echos within the left ventricular cavity.

# **Clinicopathologic Findings**

Clinical pathology tests are often noncontributory. High concentrations of circulating natriuretic peptides and cardiac troponins occur in cats with moderate to severe HCM. Variably elevated plasma TNF $_{\alpha}$  concentrations have been found in cats with CHF.

# Treatment

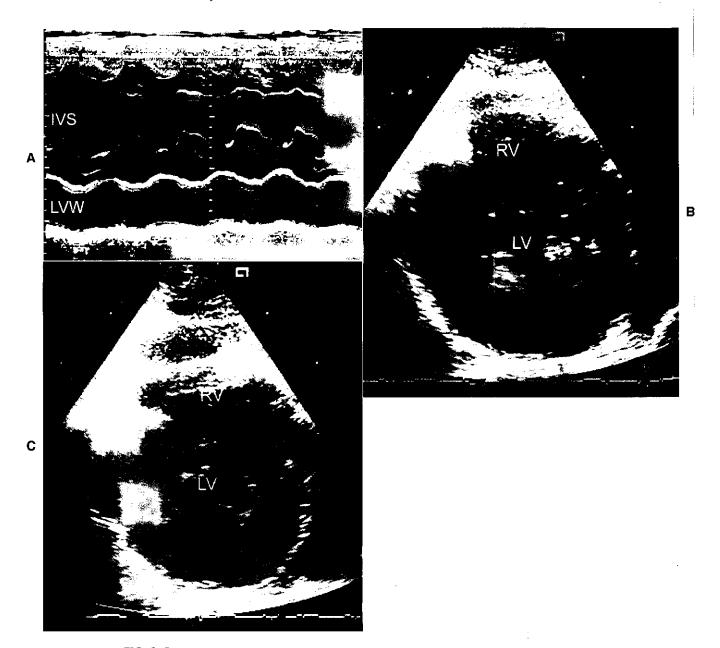

# SUBCLINICAL HYPERTROPHIC CARDIOMYOPATHY

Whether (and how) asymptomatic cats should be treated is controversial. It is unclear if disease progression can be slowed or survival prolonged by medical therapy before the onset of clinical signs. According to anecdotal reports, some cats show increased activity or improved "attitude" after being treated with a  $\beta$ -blocker or diltiazem on the basis of echocardiographic findings or an arrhythmia. When moderate to severe LA enlargement is found, especially with spontaneous echocontrast, instituting antithrombotic prophylaxis is prudent (see Chapter 12).

Avoidance of stressful situations likely to cause persistent tachycardia and reevaluation on a semiannual or annual basis are usually advised. Secondary causes of myocardial hypertrophy, such as systemic arterial hypertension and hyperthyroidism, should be ruled out (or treated, if found).

# CLINICALLY EVIDENT HYPERTROPHIC CARDIOMYOPATHY

Goals of therapy are to enhance ventricular filling, relieve congestion, control arrhythmias, minimize ischemia, and prevent thromboembolism (Box 8-1). Furosemide is used only at the dosage needed to help control congestive signs. Moderate to severe pleural effusion is treated by thoraco-

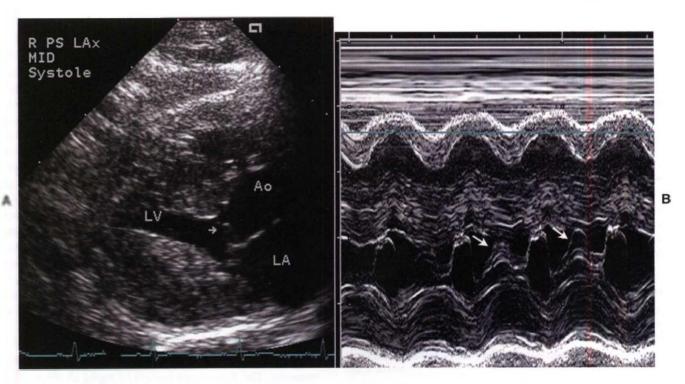

Echocardiographic examples of feline hypertrophic cardiomyopathy. M-mode image (A) at the left ventricular level from a 7-year-old male Domestic Shorthair cat. The left ventricular diastolic free-wall and septal thicknesses are about 8 mm. Two-dimensional right parasternal short-axis views during diastole (B) and systole (C) in male Maine Coon cat with hypertrophic obstructive cardiomyopathy. In (B) note the hypertrophied and bright papillary muscles. In (C) note the almost total systolic obliteration of the left ventricular chamber. IVS, interventricular septum; LV, left ventricle; LVW, left ventricular free wall; RV, right ventricle.

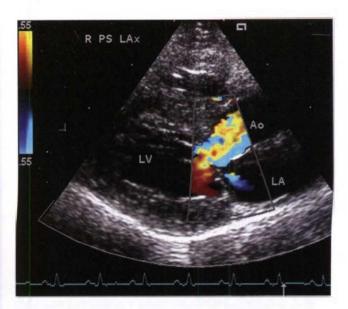

centesis, with the cat restrained gently in sternal position. Cats with severe CHF signs are given supplemental oxygen, parenteral furosemide, and sometimes other drugs to control edema (discussed in more detail later). Once initial medications have been given, the cat should be allowed to rest. The respiratory rate is noted initially and then every 30 minutes or so without disturbing the cat. Catheter placement, blood sampling, radiographs, and other tests and

therapies should be delayed until the cat's condition is more stable.

Ventricular filling is improved by slowing the heart rate and enhancing relaxation. Stress and activity level should be minimized to the extent possible. Although the Ca<sup>++</sup>-channel blocker diltiazem, or a  $\beta$ -blocker (see Chapter 4 and Table 4-2) have historically formed the foundation of long-term oral therapy, an angiotensin-converting enzyme inhibitor

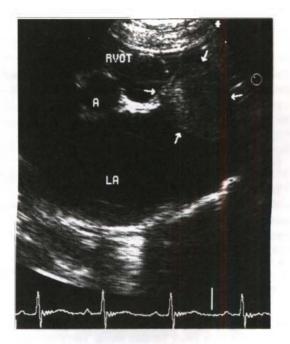

**A,** Two-dimensional echo image in midsystole from the cat in *Fig. 8-3*, *B* and *C*. Echoes from the anterior mitral leaflet appear within the LV outflow tract (arrow) because of abnormal systolic anterior (toward the septum) motion (SAM) of the valve. **B,** The M-mode echocardiogram at the mitral valve level also shows the mitral SAM (arrows). Ao, Aorta;

LA, left atrium; LV, left ventricle.

Color flow Doppler image taken in systole from a male Domestic Longhair cat with hypertrophic obstructive cardiomyopathy. Note the turbulent flow just above where the thickened interventricular septum protrudes into the left ventricular outflow tract and a small mitral insufficiency jet into the LA, common with SAM. Right parasternal long axis view. Ao, Aorta; LA, left atrium; LV, left ventricle.

Echocardiogram obtained from the right parasternal short-axis position at the aortic-left atrial level in an old male Domestic Shorthair cat with restrictive cardiomyopathy. Note the massive left atrial enlargement and thrombus (arrows) within the auricle. A, Aorta; LA, left atrium; RVOT, right ventricular outflow tract.

BOX 8-1

Treatment Outline for Cats with Hypertrophic Cardiomyopathy

#### Severe, Acute Signs of CHF\*

Supplemental O<sub>2</sub>

Minimize patient handling

Furosemide (parenteral)

Thoracocentesis, if pleural effusion present

Heart rate control and antiarrhythmic therapy, if indicated (can use IV diltiazem, esmolol, [+/-] or propranolol)†

+/- nitroglycerin (cutaneous)

+/- bronchodilator (e.g., aminophylline or theophylline)

+/- sedation

Monitor: respiratory rate, HR and rhythm, arterial blood pressure, renal function, serum electrolytes, etc.

#### Mild To Moderate Signs of CHF\*

ACE inhibitor

β-blocker (e.g., atenolol) or diltiazem

Furosemide

Antithrombotic prophylaxis (aspirin, clopidogrel, heparin, LMWH, or warfarin)‡

Exercise restriction

Reduced-salt diet, if the cat will eat it

#### Chronic HCM Management\*

ACE inhibitor

β-blocker (e.g., atenolol) or diltiazem

Furosemide (lowest effective dosage and frequency)

Antithrombotic prophylaxis (aspirin, clopidogrel, heparin, LMWH, or warfarin)‡

Thoracocentesis as needed

+/- Spironolactone and/or hydrochlorothiazide

+/- Concurrent β-blocker and diltiazem therapy

+/- Additional antiarrhythmic drug therapy, if indicated Home monitoring of resting respiratory rate (+HR if possible)

Dietary salt restriction, if accepted

Monitor renal function, electrolytes, etc.

Manage other medical problems (rule out hyperthyroidism and hypertension if not done previously)

+/- Positive inotropic drug (only for deteriorating systolic function without LV outflow obstruction)

ACE, Angiotensin-converting enzyme; CHF, congestive heart failure; HR, heart rate; LMWH, low-molecular-weight heparin.

(ACEI) may have greater benefit in cats with CHF. Optimal recommendations await further study. The decision to use one particular drug over another is influenced by echocardiographic or other findings in the individual cat or the response to medication. Diltiazem is often used when severe, symmetric LV hypertrophy is present. A β-blocker is currently preferred for cats with dynamic LV outflow obstruction, tachyarrhythmias, syncope, suspected myocardial

infarction, or concurrent hyperthyroidism. An ACEI may reduce neurohormonal activation and abnormal cardiac remodeling. It is sometimes used alone or combined with diltiazem or a  $\beta$ -blocker. Long-term therapy generally also includes therapy to reduce the likelihood of arterial thromboembolism (see Chapter 12). Dietary sodium restriction is recommended if the cat will accept such a diet, but it is more important to forestall anorexia.

Certain drugs are generally discouraged in cats with HCM. These include digoxin and other positive inotropic agents because they increase the myocardial oxygen demand and can worsen dynamic LV outflow obstruction. Any drug that accelerates the heart rate is also potentially detrimental because tachycardia shortens ventricular filling time and predisposes to myocardial ischemia. Arterial vasodilators can cause hypotension and reflex tachycardia, and cats with HCM have little preload reserve. Hypotension can also exacerbate dynamic outflow obstruction. Although ACEIs have this potential, their vasodilating effects are usually mild.

# **Diuretic Therapy**

Cats with severe pulmonary edema are usually given intramuscular (IM) furosemide initially (2 mg/kg q1-4h; see Box 3-1 and p. 58), until an IV catheter can be placed without excessive stress to the cat. The respiratory rate and effort are used to guide ongoing diuretic therapy. As respiratory distress resolves, furosemide can be continued at a reduced dose (~1 mg/kg q8-12h). Once pulmonary edema is controlled, furosemide is given orally and the dose gradually titrated downward to the lowest effective level. A starting dose of 6.25 mg/cat q8-12h can be slowly reduced over days to weeks, depending on the cat's response. Some cats do well with dosing a few times per week (or less), whereas others require it several times per day. Complications of excessive diuresis include azotemia, anorexia, electrolyte disturbances, and poor LV filling. If the cat is unable to rehydrate itself by oral water intake, cautious parenteral fluid administration may be needed (e.g., 15-20 ml/kg/day of 0.45% saline, 5% dextrose in water, or other low-sodium fluid).

# Other Therapy for Acute Congestive Heart Failure

Nitroglycerin ointment may be used (q4-6h, see Box 3-1), although no studies of its efficacy in this situation have been done. The bronchodilating and mild diuretic effects of aminophylline (5 mg/kg q12h, IM, IV) may be helpful in cats with severe pulmonary edema, as long as the drug does not increase the heart rate.

Butorphanol may be used to reduce anxiety (see Box 3-1). Acepromazine may be used as an alternative and can promote peripheral redistribution of blood by its  $\beta$ -blocking effects. Hypothermia may be exacerbated by peripheral vasodilation. Morphine should not be used in cats. Airway suctioning and mechanical ventilation with positive end-expiratory pressure can be considered in extreme cases.

Angiotensin-converting enzyme inhibitors. An ACEI appears to have beneficial effects, especially in cats with

<sup>\*</sup>See text and Chapters 3 and 4 for further details.

<sup>†</sup> See Chapter 4 for additional ventricular antiarrhythmic drug therapy.

<sup>‡</sup>See Chapter 12 for further details.

refractory heart failure. Renin-angiotensin system inhibition may mitigate angiotensin II—mediated ventricular hypertrophy. ACE inhibition might reduce LA size and ventricular/septal wall thickness, at least in some cats. Enalapril and benazepril are the agents used most often in cats, although others are available (see Chapter 3 and Table 3-3).

Ca<sup>+-</sup>-channel blockers. Ca<sup>+-</sup>-channel blockers are thought to have beneficial effects in cats with HCM by modestly reducing heart rate and contractility (which reduces myocardial O₂ demand). Diltiazem promotes coronary vasodilation and may have a positive effect on myocardial relaxation. Verapamil is not recommended because of its variable bioavailability and risk of toxicity in cats. Amlodipine has primarily vasodilatory effects and is not used for HCM because it can provoke reflex tachycardia and worsen a systolic outflow gradient.

Diltiazem is well-tolerated in many cases. Longer-acting diltiazem products are more convenient for chronic use, although the serum concentrations achieved can be variable. Dilacor (diltiazem) XR, dosed at half of an internal (60-mg) tablet from the 240-mg capsule size q24(-12)h, or Cardizem CD, compounded and dosed at 10 mg/kg q24h, are most often used.

**β-adrenergic blockers.** β-blockers can reduce heart rate and dynamic LV outflow obstruction to a greater extent than diltiazem. They are also used to suppress tachyarrhythmias in cats. Sympathetic inhibition also leads to reduced myocardial  $O_2$  demand, which can be important in cats with myocardial ischemia or infarction. By inhibiting catecholamine-induced myocyte damage, β-blockers may reduce myocardial fibrosis. β-blockers can slow active myocardial relaxation, although the benefits of heart rate reduction may outweigh this.

Atenolol (see Chapter 4) is used most commonly. Propranolol or another nonselective  $\beta$ -blocker can also be used, but these should be avoided until pulmonary edema is largely resolved. Antagonism of airway  $\beta_2$ -receptors leading to bronchoconstriction is a concern when using nonselective agents in CHF. Propranolol (a lipid soluble drug) causes lethargy and depressed appetite in some cats.

Occasionally, a  $\beta$ -blocker is added to diltiazem therapy (or vice versa) in cats with chronic refractory failure or to further reduce heart rate in cats with AF. However, care must be taken to prevent bradycardia or hypotension in animals receiving this combination.

# CHRONIC REFRACTORY CONGESTIVE HEART FAILURE

Refractory pulmonary edema or pleural effusion is difficult to manage. Moderate to large pleural effusions should be treated by thoracocentesis. Various medical strategies may help slow the rate of abnormal fluid accumulation, including maximizing the dosage of (or adding) an ACEI; increasing the dosage of furosemide (up to 4 mg/kg q8h); increasing the dose of diltiazem or  $\beta$ -blocker for greater heart rate control; and adding spironolactone, with or without hydrochlorothiazide (see Table 3-3). Spironolactone can be compounded

into a flavored suspension for more accurate dosing. Pimobendan or digoxin can also be used for treating refractory right-sided CHF signs in cats without LV outflow obstruction and those with progressive LV dilation and myocardial systolic failure in end-stage disease. Frequent monitoring for the development of azotemia or electrolyte disturbances is warranted.

# **Prognosis**

Several factors influence the prognosis for cats with HCM, including the speed with which the disease progresses, the occurrence of thromboembolic events and/or arrhythmias, and the response to therapy. Asymptomatic cats with only mild to moderate LV hypertrophy and atrial enlargement often live well for several years. Cats with marked LA enlargement and more severe hypertrophy appear to be at greater risk for CHF, thromboembolism, and sudden death. LA size and age (i.e., older cats) appear to be negatively correlated with survival. Median survival time for cats with CHF is probably between 1 to 2 years. The prognosis is worse in cats with AF or refractory right-sided CHF. Thromboembolism and CHF confer a guarded prognosis (median survival of 2 to 6 months), although some cats do well if congestive signs can be controlled and infarction of vital organs has not occurred. Recurrence of thromboembolism is common.

# SECONDARY HYPERTROPHIC MYOCARDIAL DISEASE

Myocardial hypertrophy is a compensatory response to certain identifiable stresses or diseases. Marked LV wall and septal thickening and clinical heart failure can occur in some of these cases, although they are generally not considered to be idiopathic HCM. Secondary causes should be ruled out whenever LV hypertrophy is identified.

Evaluation for hyperthyroidism is indicated in cats 6 years of age or older with myocardial hypertrophy. Hyperthyroidism alters cardiovascular function by its direct effects on the myocardium and through the interaction of heightened sympathetic nervous system activity and excess thyroid hormone on the heart and peripheral circulation. Cardiac effects of thyroid hormone include myocardial hypertrophy and increased heart rate and contractility. The metabolic acceleration that accompanies hyperthyroidism causes a hyperdynamic circulatory state characterized by increased cardiac output, oxygen demand, blood volume, and heart rate. Systemic hypertension can further stimulate myocardial hypertrophy. Manifestations of hyperthyroid heart disease often include a systolic murmur, hyperdynamic arterial pulses, a strong precordial impulse, sinus tachycardia, and various arrhythmias. Criteria for IV enlargement or hypertrophy are often found on ECG, thoracic radiographs, or echocardiogram. Signs of CHF develop in approximately 15% of hyperthyroid cats; most have normal to high FS, but a few have poor contractile function. Cardiac therapy, in addition to treatment of the hyperthyroidism, may be necessary for these cats. A  $\beta$ -blocker can temporarily control many of the adverse cardiac effects of excess thyroid hormone, especially tachyarrhythmias. Diltiazem is an alternative therapy. Treatment for CHF is the same as that described for HCM. The rare hypodynamic (dilated) cardiac failure is treated in the same way as dilated cardiomyopathy. Cardiac therapy, including a  $\beta$ -blocker, is not a substitute for antithyroid treatment.

IV concentric hypertrophy is the expected response to increased ventricular systolic pressure (afterload). Systemic arterial hypertension (see Chapter 11) increases afterload because of high arterial pressure and resistance. Increased resistance to ventricular outflow also occurs with a fixed (e.g., congenital) subaortic stenosis or dynamic LV outflow tract obstruction (hypertrophic obstructive cardiomyopathy). Cardiac hypertrophy also develops in cats with hypersomatotropism (acromegaly) as a result of growth hormone's trophic effects on the heart. CHF occurs in some of these cats. Increased myocardial thickness occasionally results from infiltrative myocardial disease, most notably from lymphoma.

# RESTRICTIVE CARDIOMYOPATHY

# **Etiology and Pathophysiology**

Restrictive cardiomyopathy (RCM) is associated with extensive endocardial, subendocardial, or myocardial fibrosis. The cause is not clear but probably is multifactorial. This condition may be a consequence of endomyocarditis or the endstage of myocardial failure and infarction caused by HCM. Neoplastic (e.g., lymphoma) or other infiltrative or infectious diseases occasionally causes a secondary RCM.

There are a variety of histologic findings in cats with RCM, including marked perivascular and interstitial fibrosis, intramural coronary artery narrowing, and myocyte hypertrophy, as well as areas of degeneration and necrosis. Some cats have extensive LV endomyocardial fibrosis with chamber deformity, or fibrous tissue bridging between the septum and LV wall. The mitral apparatus and papillary muscles may be fused to surrounding tissue or distorted.

LA enlargement is prominent in cats with RCM, as a consequence of chronically high LV filling pressure from increased LV wall stiffness. The LV may be normal to reduced in size or mildly dilated. LV hypertrophy is variably present and may be regional. Intracardiac thrombi and systemic thromboembolism are common.

LV fibrosis impairs diastolic filling. Most affected cats have normal to only mildly reduced contractility, but this may progress with time as more functional myocardium is lost. Some cases develop regional LV dysfunction, possibly from myocardial infarction, which decreases overall systolic function. These cases are perhaps better considered unclassified rather than restrictive. If mitral regurgitation is present, it is usually mild. Arrhythmias, ventricular dilation, and myocardial ischemia or infarction also contribute to the development of diastolic dysfunction. Chronically elevated

left heart filling pressures, combined with compensatory neurohormonal activation, leads to left-sided or biventricular CHF. The duration of subclinical disease progression in RCM is unknown.

## **Clinical Features**

Middle-aged and older cats are most often diagnosed with RCM. Young cats are sometimes affected. Inactivity, poor appetite, vomiting, and weight loss of recent onset are common in the history. The clinical presentation varies but usually includes respiratory signs from pulmonary edema or pleural effusion. Clinical signs are often precipitated or acutely worsened by stress or concurrent disease that causes increased cardiovascular demand. Thromboembolic events are also common. Sometimes the condition is discovered by detecting abnormal heart sounds or arrhythmias on routine exam or radiographic evidence of cardiomegaly.

A systolic murmur of mitral or tricuspid regurgitation, a gallop sound, and arrhythmias are common physical examination findings. Pulmonary sounds can be abnormal in cats with pulmonary edema or pleural effusion. Femoral arterial pulses are normal or slightly weak. Jugular vein distention and pulsation are common in cats with right-sided CHF signs. Acute signs of distal aortic (or other) thromboembolism may be the reason for presentation.

# Diagnosis

Diagnostic test results are frequently similar to those in cats with HCM. Radiographs indicate LA or biatrial enlargement (sometimes massive) and LV or generalized heart enlargement (Fig. 8-7). Mild to moderate pericardial effusion contributes to the cardiomegaly in some cats. Proximal pulmonary veins may appear dilated and tortuous. Other possible radiographic findings in cats with CHF signs include infiltrates of pulmonary edema, pleural effusion, and sometimes hepatomegaly.

Common ECG abnormalities include wide QRS complexes, tall R waves, evidence of intraventricular conduction disturbances, wide P waves, and atrial tachyarrhythmias or fibrillation. Echocardiography typically shows marked LA (and sometimes right atrial [RA]) enlargement. There is variable LV wall and interventricular septal thickening. Ventricular wall motion is often normal but may be somewhat depressed (FS usually >25%). Hyperechoic areas of fibrosis within the LV wall and/or endocardial areas may be evident. Extraneous intraluminal echos representing excess moderator bands are occasionally seen. Sometimes, extensive LV endocardial fibrosis, with scar tissue bridging between the free-wall and septum, constricts part of the ventricular chamber. Right ventricular (RV) dilation is often seen. Sometimes an intracardiac thrombus is found, usually in the left auricle or left atrium, but occasionally in the left ventricle (see Fig. 8-6). Mild mitral or tricuspid regurgitation and a restrictive mitral inflow pattern can be seen with Doppler studies. Some cats have marked regional wall dysfunction, especially of the left ventricular free wall, which depresses FS, along with mild left ventricular dilation. These

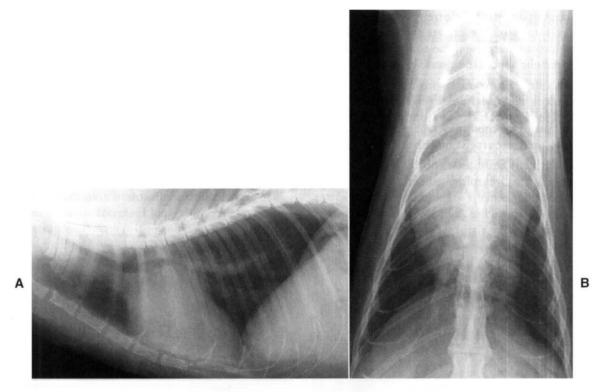

FIG 8-7
Lateral (A) and dorsoventral (B) radiographs from an older Domestic Shorthair cat with restrictive cardiomyopathy show marked left atrial enlargement and prominent proximal pulmonary veins.

may represent cases of myocardial infarction or unclassified cardiomyopathy rather than RCM.

The clinicopathologic findings are nonspecific. Pleural effusions are usually classified as modified transudate or chyle. Plasma taurine concentration is low in some affected cats and should be measured if decreased contractility is identified.

# **Treatment and Prognosis**

Therapy for acute CHF is the same as for cats with HCM (see p. 148). Cats that require inotropic support can be given dobutamine by constant rate infusion (CRI). Management of thromboembolism is described on p. 197.

Long-term therapy for heart failure includes furosemide at the lowest effective dosage; the resting respiratory rate, activity level, and radiographic findings are used to monitor efficacy. An ACEI is also used, starting with a very low dose and increasing to the usual maintenance dose (see Table 3-3). Ideally, blood pressure should be monitored when initiating or adjusting this therapy. A  $\beta$ -blocker is usually used for tachyarrhythmias or if myocardial infarction is suspected. Alternatively, diltiazem can also be used, although its value in the face of significant fibrosis is controversial. Cats that need chronic inotropic support can be given digoxin or pimobendan (see Table 3-3). Taurine supplementation may be helpful. Prophylaxis against thromboembolism is recommended (see p. 199), and a low-sodium diet should be fed, if accepted. Creatinine or the blood urea nitrogen and elec-

trolyte concentrations should be measured periodically. Furosemide and/or enalapril doses should be reduced if hypotension or azotemia occurs.

Cats with refractory heart failure and pleural effusion are difficult to manage. In addition to thoracocentesis as needed, the ACEI and furosemide dosages can be increased cautiously. Adding digoxin or pimobendan, if not already being used, may be helpful for cats with refractory failure. Other strategies include adding spironolactone (with or without hydrochlorothiazide) or nitroglycerin ointment to the regimen.

The prognosis is generally guarded to poor for cats with RCM and heart failure. Nevertheless, some cats survive more than a year after diagnosis. Thromboembolism and refractory pleural effusion commonly occur.

# **DILATED CARDIOMYOPATHY**

# Etiology

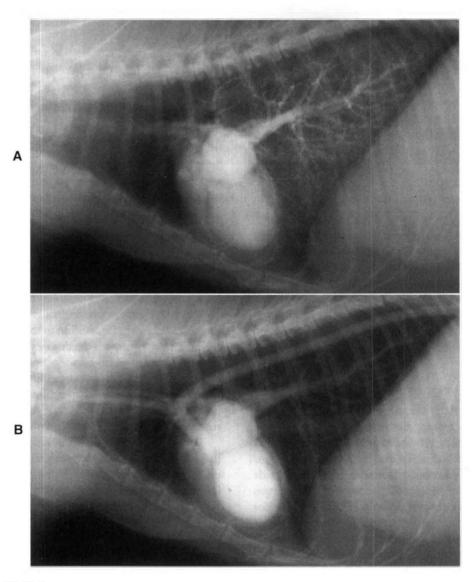

In the late 1980s taurine deficiency was identified as a major cause of dilated cardiomyopathy (DCM) in cats. This discovery prompted pet food manufacturers to increase the taurine content of commercial cat diets. Clinical DCM then became an uncommon disease in cats. Not all cats fed a taurine-deficient diet develop DCM. Other factors besides a simple deficiency of this essential amino acid are likely to be involved in the pathogenesis, including genetic factors and a possible

link with potassium depletion. Relatively few cases of DCM are identified now; many of these cats are not taurine deficient. DCM in these cats may represent the end-stage of another myocardial metabolic abnormality, toxicity, or infection.

Doxorubicin causes characteristic myocardial histologic lesions in cats as it does in dogs. Cats appear less likely to develop clinical CHF from myocardial failure. Although in very rare cases cats have echocardiographic changes consistent with DCM after receiving cumulative doses of 170 to 240 mg/m², clinically relevant doxorubicin-induced cardiomyopathy does not occur in the cat.

# **Pathophysiology**

DCM in cats has a similar pathophysiology to that in dogs (see p. 129). Poor myocardial contractility is the characteristic feature (Fig. 8-8). Usually, all cardiac chambers become dilated. AV valve insufficiency occurs secondary to chamber enlargement and papillary muscle atrophy. As cardiac output decreases, compensatory neurohormonal mechanisms are activated, leading eventually to signs of CHF and low cardiac output. Besides pulmonary edema, pleural effusion and arrhythmias are common in cats with DCM.

Nonselective angiogram from a 13-year-old female Siamese cat with dilated cardiomyopathy. A bolus of radiographic contrast material was injected into the jugular vein. **A,** Three seconds after injection, some contrast medium remains in the right ventricle and pulmonary vasculature. Dilated pulmonary veins are seen entering the left atrium. Note the dilated left atrium and ventricle. **B,** Thirteen seconds after the injection, the left heart and pulmonary veins are still opacified, illustrating the poor cardiac contractility and extremely slow circulation time. The thin left ventricular caudal wall and papillary muscles are better seen in this frame.

# **Clinical Features**

DCM can occur at any age, although most affected cats are late-middle aged to geriatric. There is no breed or gender predilection. Clinical signs often include anorexia, lethargy, increased respiratory effort or dyspnea, dehydration, and hypothermia. Subtle evidence of poor ventricular function is usually found in conjunction with signs of respiratory compromise. Jugular venous distention, an attenuated precordial impulse, weak femoral pulses, a gallop sound (usually S<sub>3</sub>), and a left or right apical systolic murmur (of mitral or tricuspid regurgitation) are common. Bradycardia and arrhythmias are frequently heard, although many cats have a normal sinus rhythm. Increased lung sounds and pulmonary crackles can be auscultated in some cats, but pleural effusion may muffle ventral lung sounds. Some cats have signs of arterial thromboembolism (see p. 195).

# Diagnosis

Generalized cardiomegaly with rounding of the cardiac apex is often seen on radiographs. Pleural effusion is common and may obscure the heart shadow and co-existing evidence of pulmonary edema or venous congestion. Hepatomegaly may be detected; ascites is occasionally found.

Typical ECG findings include a LV enlargement pattern, AV conduction disturbance, and tachyarrhythmias. Echocardiography is an important tool to differentiate DCM from other myocardial pathophysiology. Findings are analogous to those in dogs with DCM (see p. 131). Some cats have areas of focal hypertrophy with hypokinesis of only the LV wall or septum. These may represent indeterminant myocardial disease rather than typical DCM. An intracardiac thrombus is identified in some cats, more often within the left atrium.

Nonselective angiocardiography is a more risky alternative to echocardiography, as with other cardiomyopathies. Characteristic angiographic findings include generalized chamber enlargement, atrophied papillary muscles, small aortic diameter, and slow circulation time (see Fig. 8-8). Complications of angiography, especially in cats with poor myocardial function or CHF, include vomiting and aspiration, arrhythmias, and cardiac arrest. The pleural effusion in cats with DCM is usually a modified transudate, although it can be chylous. Prerenal azotemia, mildly increased liver enzyme activity, and a stress leukogram are common clinicopathologic findings. Cats with arterial thromboembolism often have high serum muscle enzyme activities and may have an abnormal hemostasis profile. Plasma or whole blood taurine concentration measurement is recommended. Specific instructions for sample collection and mailing should be obtained from the specific laboratory. Plasma taurine concentrations are influenced by the amount of taurine in the diet, the type of diet, and the time of sampling in relation to eating; however, a plasma taurine concentration of 20 to 30 nmol/ml or less in a cat with DCM is diagnostic for taurine deficiency. Non-anorexic cats with a plasma taurine concentration of <60 nmol/ml probably should receive taurine supplementation or a different diet. Whole blood samples produce more consistent results than plasma

samples. Normal whole blood taurine concentrations exceed 200 nmol/ml; <140 nmol/ml is considered deficient.

# **Treatment and Prognosis**

The goals of treatment are analogous to those for dogs with DCM. Pleural fluid is removed by thoracocentesis. In cats with acute CHF, furosemide is given to promote diuresis, as described for HCM. Overly aggressive diuresis is discouraged because it can markedly reduce cardiac output in these cases with poor systolic function. Supplemental O2 is recommended. The venodilator nitroglycerin may be helpful in cats with severe pulmonary edema. ACEI therapy is begun as soon as oral medication can be safely given. Other vasodilators (nitroprusside, hydralazine, or amlodipine) may help maximize cardiac output, although they increase the risk of hypotension (see Box 3-1). Blood pressure, hydration, renal function, electrolyte balance, and peripheral perfusion should be monitored closely. Hypothermia is common in cats with decompensated DCM; external warming is provided as needed.

Positive inotropic support is indicated. Dobutamine (or dopamine) is administered by CRI for critical cases (see p. 60 and Box 3-1). Possible adverse effects include seizures or tachycardia; if they occur, the infusion rate is decreased by 50% or discontinued. Oral inotropic therapy with pimobendan or digoxin (see p. 65 and Table 3-3) for maintenance therapy may be instituted. Digoxin tablets are usually used because the elixir is distasteful to many cats. Toxicity can easily occur, especially in cats receiving concurrent drug therapy; serum digoxin concentration should be monitored if this drug is used (see p. 66).

Sometimes the diuretic and vasodilator therapy used for acute CHF leads to hypotension and can predispose to cardiogenic shock in cats with DCM. Half-strength saline solution with 2.5% dextrose or other low-sodium fluids can be used intravenously with caution to help support blood pressure (e.g., 20 to 35 ml/kg/day in several divided doses or by CRI); potassium supplementation may be needed. Fluid can be administered subcutaneously if necessary, although its absorption from the extravascular space may be impaired in these cases.

Chronic therapy for DCM in cats that survive acute CHF includes oral furosemide (tapered to the lowest effective dosage), an ACEI, pimobendan or digoxin, antithrombotic prophylaxis (p. 199), and (if the patient is taurine deficient) supplemental taurine or a high-taurine diet. Taurine supplementation is instituted as soon as practical, at 250 to 500 mg orally q12h, when plasma taurine concentration is low or cannot be measured. Clinical improvement, if it occurs, is generally not apparent until after the first 1 to 2 weeks of taurine supplementation, so supportive cardiac care is vital.

Improved systolic function is seen echocardiographically within 6 weeks of starting taurine supplementation in most taurine-deficient cats. Drug therapy may become unnecessary in some cats after 6 to 12 weeks, but resolution of pleural effusion and pulmonary edema should be confirmed before weaning the cat from medications. If normal systolic func-

tion, based on echocardiography, returns, the patient can be slowly weaned from supplemental taurine as long as a diet known to support adequate plasma taurine concentrations (e.g., most name-brand commercial foods) is consumed. Dry diets with 1000 to 1200 mg of taurine per kilogram of dry weight and canned diets with 2000 to 2500 mg of taurine per kilogram of dry weight are thought to maintain normal plasma taurine concentrations in adult cats. Reevaluation of the plasma taurine concentration 2 to 4 weeks after discontinuing the supplement is advised.

Taurine-deficient cats that survive a month after initial diagnosis often can be weaned from all or most medications and appear to have approximately a 50% chance for 1-year survival. The prognosis for cats that do not receive taurine supplements or do not respond to taurine is guarded to poor. Thromboembolism in cats with DCM is a grave sign.

#### OTHER MYOCARDIAL DISEASES

# ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an idiopathic cardiomyopathy that is similar to the uncommon ARVC in people. Characteristic features include moderate to severe RV chamber dilation, with either focal or diffuse RV wall thinning. RV wall aneurysm is also common. Dilation of the right atrium and, less commonly, the left atrium may occur. Myocardial atrophy with fatty and/or fibrous replacement tissue, focal myocarditis, and evidence of apoptosis are typical histologic findings. These are most prominent in the RV wall. Fibrous tissue or fatty infiltration is sometimes found in the LV and atrial walls.

Signs of right-sided CHF are common, with labored respirations caused by pleural effusion, jugular venous distention, ascites or hepatosplenomegaly, and occasionally syncope. Lethargy and inappetence without overt heart failure are sometimes the presenting signs.

Thoracic radiographs indicate right heart and sometimes LA enlargement. Pleural effusion is common. Ascites, caudal vena caval distention, and evidence of pericardial effusion may also occur. The ECG can document various arrhythmias in affected cats, including ventricular premature complexes (VPCs), ventricular tachycardia, AF, and supraventricular tachyarrhythmias. A right bundle branch block pattern appears to be common; some cats have first-degree AV block. Echocardiography shows severe RA and RV enlargement. Other possible findings include abnormal muscular trabeculation, aneurysmal dilation, areas of dyskinesis, and paradoxical septal motion. Tricuspid regurgitation appears to be a consistent finding on Doppler exam.

The prognosis is guarded once signs of heart failure appear. Recommended therapy includes diuretics as necessary, an ACEI, and digoxin (or pimobendan). Additional antiarrhythmic therapy may be needed (see Chapter 4). In people with ARVC, various tachyarrhythmias are a prominent feature and sudden death is common.

# CORTICOSTEROID-ASSOCIATED HEART FAILURE

Some cats develop CHF after receiving corticosteroid therapy. It is unclear whether this represents a previously unrecognized form of feline heart failure, unrelated to preexisting HCM, hypertension, or hyperthyroidism. An acute onset of lethargy, anorexia, tachypnea, and respiratory distress is described in affected cats. Most cats have normal auscultatory findings without tachycardia.

Moderate cardiomegaly, with diffuse pulmonary infiltrates and mild or moderate pleural effusion, appears to be typical on radiographic examination. Possible ECG findings include sinus bradycardia, intraventricular conduction abnormalities, atrial standstill, atrial fibrillation, and VPCs. On echocardiogram, most affected cats have some degree of LV wall or septal hypertrophy and LA enlargement. Some have AV valve insufficiency or abnormal systolic mitral motion.

CHF is treated in the same way as HCM; corticosteroids should be discontinued. Partial resolution of abnormal cardiac findings and successful weaning from cardiac medications are reported in some cats.

#### **MYOCARDITIS**

Inflammation of the myocardium and adjacent structures may occur in cats, as it does in other species (see also p. 137). In one study myocarditis was histologically identified in samples from more than half of cardiomyopathic cats but none from cats in the control group; viral DNA (panleukopenia) was found in about one third of the cats with myocarditis. However, the possible role of viral myocarditis in the pathogenesis of cardiomyopathy is not clear. Severe, widespread myocarditis may cause CHF or fatal arrhythmias. Cats with focal myocardial inflammation may be asymptomatic. Acute and chronic viral myocarditis have been suspected. A viral cause is rarely documented, although feline coronavirus has been identified as a cause of pericarditis-epicarditis.

Endomyocarditis has been documented mostly in young cats. Acute death, with or without preceding signs of pulmonary edema for 1 to 2 days, is the most common presentation. Histopathologic characteristics of acute endomyocarditis include focal or diffuse lymphocytic, plasmacytic, and histiocytic infiltrates with few neutrophils. Myocardial degeneration and lysis are seen adjacent to the infiltrates. Chronic endomyocarditis may have a minimal inflammatory response but much myocardial degeneration and fibrosis. RCM could represent the end stage of nonfatal endomyocarditis. Therapy involves managing CHF signs and arrhythmias, and other supportive care.

Bacterial myocarditis may develop in association with sepsis or as a result of bacterial endocarditis or pericarditis. Experimental *Bartonella* sp. infection can cause subclinical lymphoplasmacytic myocarditis, but it is unclear whether natural infection plays a role in the development of cardiomyopathy in cats. *Toxoplasma gondii* occasionally has been associated with myocarditis, usually in immunosuppressed

cats as part of a generalized disease process. Traumatic myocarditis is recognized infrequently in cats.

CONSTRICTIVE PERICARDIAL DISEASE

CARDIAC TUMORS

#### GENERAL CONSIDERATIONS

Several diseases of the pericardium and intrapericardial space can disrupt cardiac function. Normally, the pericardium anchors the heart in place and provides a barrier to infection or inflammation from adjacent tissues. The pericardium is a closed serosal sac that envelops the heart and is attached to the great vessels at the heartbase. Directly adhered to the heart is the visceral pericardium, or epicardium, which is composed of a thin layer of mesothelial cells. This layer reflects back over itself at the base of the heart to line the outer fibrous parietal layer. A small amount (~0.25 ml/kg body weight) of clear, serous fluid normally serves as a lubricant between these layers. The pericardium helps balance the output of the right and left ventricles and limits acute distention of the heart, although there are few overt clinical consequences associated with its removal.

Excess or abnormal fluid accumulation in the pericardial sac is the most common pericardial disorder, and it occurs

most often in dogs. Other acquired and congenital pericardial diseases are seen infrequently. Acquired pericardial disease causing clinical signs is uncommon in cats.

#### CONGENITAL PERICARDIAL DISORDERS

#### PERITONEOPERICARDIAL DIAPHRAGMATIC HERNIA

Peritoneopericardial diaphragmatic hernia (PPDH) is the most common pericardial malformation in dogs and cats. It occurs when abnormal embryonic development (probably of the septum transversum) allows persistent communication between the pericardial and peritoneal cavities at the ventral midline. The pleural space is not involved. Other congenital defects, such as umbilical hernia, sternal malformations, and cardiac anomalies may co-exist with PPDH. Abdominal contents herniate into the pericardial space to a variable degree and cause associated clinical signs. Although the peritoneal-pericardial communication is not trauma induced, trauma can facilitate movement of abdominal contents through a preexisting defect.

#### **Clinical Features**

The initial onset of clinical signs associated with PPDH can occur at any age (ages between 4 weeks and 15 years have been reported). The majority of cases are diagnosed during the first 4 years of life, usually within the first year. In some animals clinical signs never develop. Males appear to be affected more frequently than females, and Weimaraners may be predisposed. The malformation is common in cats as well.

Clinical signs usually relate to the gastrointestinal (GI) or respiratory system. Vomiting, diarrhea, anorexia, weight loss, abdominal pain, cough, dyspnea, and wheezing are most often reported; shock and collapse may also occur. Possible physical examination findings include muffled heart sounds on one or both sides of the chest; displacement or attenuation of the apical precordial impulse; an "empty" feel on abdominal palpation (with herniation of many organs); and, rarely, signs of cardiac tamponade (discussed in more detail later).

#### Diagnosis

Thoracic radiographs are often diagnostic or highly suggestive of PPDH. Enlargement of the cardiac silhouette, dorsal tracheal displacement, overlap of the diaphragmatic and caudal heart borders, and abnormal fat and/or gas densities within the cardiac silhouette are characteristic findings (Fig. 9-1, A and B). A pleural fold, extending between the caudal heart shadow and the diaphragm ventral to the caudal vena cava on lateral view, is usually evident. Gas-filled loops of bowel crossing the diaphragm into the pericardial sac, a small liver, and few organs within the abdominal cavity may also be seen. Echocardiography helps confirm the diagnosis when radiographic findings are equivocal (Fig. 9-2). A GI barium series is diagnostic if the stomach and/or intestines are in the pericardial cavity (Fig. 9-1, C). Fluoroscopy, nonselective angiography (especially if only falciform fat or liver has herniated), celiography, or pneumopericardiography also can aid in diagnosis. ECG changes are inconsistent; decreased amplitude complexes and axis deviations caused by cardiac position changes sometimes occur.

#### **Treatment**

Therapy involves surgical closure of the peritoneal-pericardial defect after viable organs are returned to their normal location. The presence of other congenital abnormalities and the animal's clinical signs influence the decision to operate. The prognosis in uncomplicated cases is excellent. Older animals without clinical signs may do well without surgery, especially because organs chronically adhered to the heart or pericardium may be traumatized during attempted repositioning.

#### **OTHER PERICARDIAL ANOMALIES**

Pericardial cysts are rare anomalies. They may originate from abnormal fetal mesenchymal tissue or from incarcerated omental or falciform fat associated with a small PPDH. The

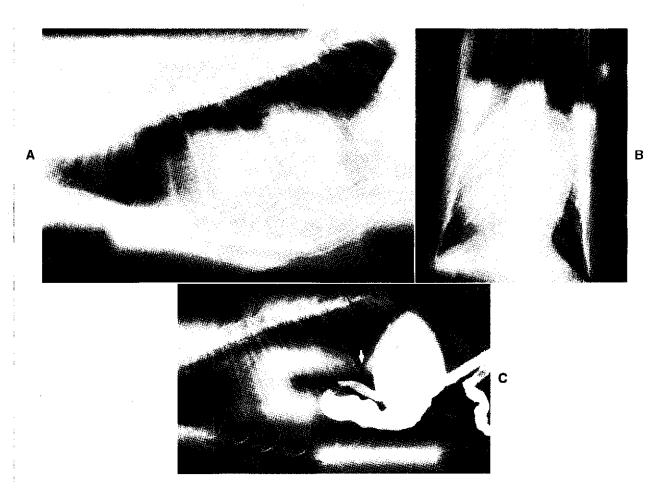

FIG 9-1

Lateral **(A)** and dorsoventral **(B)** radiographs from a 5-year-old male Persian cat with a congenital peritoneopericardial diaphragmatic hernia (PPDH). Note the greatly enlarged cardiac silhouette containing fat, soft tissue, and gas densities as well as tracheal elevation. There is overlap between the cardiac and diaphragmatic borders on both views. Presence of a portion of the stomach and duodenum within the pericardium is evident after barium administration **(C)**; omental fat and liver are also present within the pericardial sac. In **C**, the dorsal pleural fold between pericardium and diaphragm is best appreciated (arrow).

FIG 9-2
Right parasternal short-axis echocardiogram from a female Persian cat with peritoneopericardial diaphragmatic hernia [PPDH]. The pericardium (PERI), indicated by arrows, surrounds liver and omental tissue as well as the heart. LV, Left ventricle.

pathophysiologic signs and clinical presentation can mimic those seen with pericardial effusion. Radiographically, the cardiac silhouette may appear enlarged and deformed. Echocardiography or pneumopericardiography can reveal the diagnosis. Surgical cyst removal, combined with partial pericardiectomy, usually resolves the clinical signs.

Congenital defects of the pericardium itself are extremely rare in dogs and cats; most are incidental postmortem findings. Sporadic cases of partial (usually left-sided) or complete absence of the pericardium are reported. A possible complication of partial absence of the pericardium is herniation of a portion of the heart; this could cause syncope, embolic disease, or sudden death. Echocardiography or angiocardiography may allow antemortem diagnosis.

#### PERICARDIAL EFFUSION

#### **Etiology and Types Of Fluid**

In dogs most pericardial effusions are serosanguineous or sanguineous and are of neoplastic or idiopathic origin. Transudates, modified transudates, and exudates are found occasionally in both dogs and cats.

#### **HEMORRHAGE**

Hemorrhagic effusions are common in dogs. The fluid usually appears dark red, with a packed cell volume (PCV) >7%, a specific gravity >1.015, and a protein concentration >3 g/dl. Cytologic analysis shows mainly red blood cells, but reactive mesothelial, neoplastic, or other cells may be seen.

The fluid does not clot unless hemorrhage was very recent. Neoplastic hemorrhagic effusions are more likely in dogs older than 7 years. Middle-aged, large-breed dogs are most likely to have idiopathic "benign" hemorrhagic effusion.

Hemangiosarcoma (HSA) is by far the most common neoplasm causing hemorrhagic pericardial effusion in dogs; it is uncommon in cats. Hemorrhagic pericardial effusion also occurs in association with various heartbase tumors; pericardial mesotheliomas; malignant histiocytosis (MH); and, rarely, metastatic carcinoma. HSAs (see p. 167) usually arise within the right heart, especially in the right auricular appendage. Chemodectoma is the most common heartbase tumor; it arises from chemoreceptor cells at the base of the aorta. Thyroid, parathyroid, lymphoid, and connective tissue neoplasms also occur at the heartbase. Pericardial mesothelioma develops in some dogs and cats and may mimic idiopathic disease. Lymphoma involving various parts of the heart is seen more often in cats than in dogs. Dogs with MH and pericardial effusion usually have pleural effusion and ascites despite the fact that they do not have cardiac tamponade.

Idiopathic (benign) pericardial effusion is reported most frequently in medium- to large-breed dogs. Golden Retrievers, Labrador Retrievers, and Saint Bernards may be predisposed. Although dogs of any age can be affected, the median age is 6 to 7 years. More cases have been reported in males than females. Mild pericardial inflammation, with diffuse or perivascular fibrosis and focal hemorrhage, is common on histologic exam. Layers of fibrosis suggest a recurrent process in some cases. Constrictive pericardial disease is a potential complication.

Other, less common causes of intrapericardial hemorrhage include left atrial rupture secondary to severe mitral insufficiency (see p. 116), coagulopathy, penetrating trauma (including iatrogenic laceration of a coronary artery during pericardiocentesis), and possibly uremic pericarditis.

#### **TRANSUDATES**

Pure transudates are clear, with a low cell count (usually <1000 cells/µl), specific gravity (<1.012), and protein content (<2.5 g/dl). Modified transudates may appear slightly cloudy or pink tinged. Their cellularity (~1000 to 8000 cells/µl) is still low, but total protein concentration (~2.5-5.0 g/dl) and specific gravity (1.015-1.030) are higher than those of a pure transudate. In some dogs and cats, transudative effusions occur with congestive heart failure (CHF), hypoalbuminemia, PPDH and pericardial cysts, and toxemias that increase vascular permeability (including uremia). These conditions usually are associated with relatively small-volume pericardial effusion; cardiac tamponade is rare.

#### **EXUDATES**

Exudative effusions are cloudy to opaque or serofibrinous to serosanguineous. They typically have a high nucleated cell count (usually much higher than 3000 cells/µl), protein content (often much above 3 g/dl), and specific gravity (>1.015). Cytologic findings are related to the etiology. Exudative pericardial effusions are found only rarely in small animals, except in cats with feline infectious peritonitis (FIP).

Infectious pericarditis is usually related to plant awn migration, bite wounds, or extension of a pleural or mediastinal infection. Various bacteria (aerobic and anaerobic), actinomycosis, coccidioidomycosis, disseminated tuberculosis, and, rarely, systemic protozoal infections have been identified. Sterile exudative effusions are reported with leptospirosis, caninc distemper, and idiopathic pericardial effusion in dogs and with FIP and toxoplasmosis in cats. FIP is the most important cause of symptomatic pericardial effusion in cats. Chronic uremia occasionally causes a sterile, serofibrinous or hemorrhagic effusion.

#### **Pathophysiology**

Fluid accumulation within the pericardial space causes clinical signs when it raises intrapericardial pressure to or above normal cardiac filling pressure. This accumulation impedes venous return and cardiac filling. As long as intrapericardial pressure remains low, cardiac filling and output remain relatively normal. If fluid accumulates slowly, the pericardium may distend enough to accommodate the increased effusate volume at relatively low pressure. However, pericardial tissue is relatively noncompliant. Rapid fluid accumulation or a very large effusion causes a steep rise in intrapericardial pressure, leading to cardiac tamponade. Pericardial fibrosis and thickening further limit the compliance of this tissue.

Pericardial effusion of very large volume may cause clinical signs by virtue of its size, even without overt cardiac

tamponade. Lung and/or tracheal compression can compromise ventilation and stimulate cough; esophageal compression can cause dysphagia or regurgitation.

#### CARDIAC TAMPONADE

Cardiac tamponade develops when pericardial fluid accumulation raises intrapericardial pressure to or above the normal cardiac diastolic pressure. This external compression of the heart progressively limits filling, initially of the right heart, then the left. Cardiac output subsequently falls while systemic venous pressure rises. Pressure in all cardiac chambers and the great veins eventually becomes equilibrated during diastole. Neurohormonal compensatory mechanisms are activated as tamponade develops. Gradual pericardial fluid accumulation results in signs of CHF because of compensatory volume retention and the direct effects of impaired cardiac filling. Manifestations of systemic venous congestion and right-sided CHF (ascites and pleural effusion) usually predominate because of the right heart's thinner wall and low pressures. Pericardial effusion does not typically affect cardiac contractility directly, but reduced coronary perfusion during tamponade can impair both systolic and diastolic function. Low cardiac output, arterial hypotension, and poor organ perfusion can ultimately lead to cardiogenic shock and death.

The rate of pericardial fluid accumulation and the distensibility of the pericardial sac determine whether and how quickly cardiac tamponade develops. Rapid accumulation of even a relatively small volume can raise intrapericardial pressure sharply. A gradual process is implied when the pericardial fluid volume is large. Cardiac tamponade is relatively common in dogs but rare in cats.

Pulsus paradoxus is the term used to describe the exaggerated variation in arterial blood pressure that occurs during the respiratory cycle as a result of cardiac tamponade. During inspiration intrapericardial and right atrial (RA) pressures fall, which facilitates right heart filling and pulmonary blood flow. At the same time, left heart filling is reduced as more blood is held in the lungs and the interventricular septum bulges leftward from the inspiratory increase in right ventricular (RV) filling; consequently, left heart output and systemic arterial pressure decrease during inspiration. The variation in systolic arterial pressure between inspiration and expiration is usually >10 mm Hg in patients with cardiac tamponade and pulsus paradoxus. Pulsus paradoxus is not always discernible using palpation of the femoral pulse.

#### Clinical Features

Clinical findings in patients with cardiac tamponade usually reflect right-sided CHF as well as poor cardiac output. Before obvious ascites develops, possible nonspecific signs include lethargy, weakness, poor exercise tolerance, and inappetence. The history typically includes complaints of weakness, exercise intolerance, abdominal enlargement, tachypnea, syncope, and cough. A history of collapse is more common in dogs with neoplastic disease; dogs without a mass lesion are more

FIG 9-3
Older male Boxer with chronic cardiac tamponade and right-sided congestive heart failure secondary to chemodectoma. The abdomen is greatly distended with ascites; chronic loss of lean body mass is evident along the spine, pelvis, and rib cage.

likely to have obvious ascites. Marked loss of lean body mass occurs in some chronic cases (Fig. 9-3).

Jugular vein distention and/or positive hepatojugular reflux, hepatomegaly, ascites, labored respirations, and weak femoral pulses are common physical examination findings. Pleural effusion and ascites are also common in cats, as well as dogs, with cardiac tamponade. A palpable decrease in arterial pulse strength during inspiration (pulsus paradoxus) might be discernible in some dogs with tamponade. Sinus tachycardia, pale mucous membranes, and prolonged capillary refill time are manifestations of high sympathetic tone. The precordial impulse is weak when the pericardial fluid volume is large. Heart sounds are muffled in patients with moderate to large pericardial effusions. Lung sounds are muffled over the ventral thorax in those with pleural effusion. Although pericardial effusion does not cause a murmur, concurrent cardiac disease may do so. If fluid has rapidly accumulated, acute tamponade can lead to shock and death without obvious signs of pleural effusion, ascites, or radiographic evidence of cardiomegaly. In such cases, jugular venous distention, hypotension, and pulmonary edema may be evident. Infectious pericarditis may be accompanied by fever; rarely, a pericardial friction rub might be heard.

#### **Diagnosis**

A central venous pressure (CVP) above 10 to 12 cm  $H_2O$  is common; normally, CVP is <8 cm  $H_2O$ . CVP measurement is helpful when the jugular veins are difficult to assess or it is unclear whether right heart filling pressure is elevated. Moderate- to large-volume pleural effusion should be drained before CVP measurement, not only to stabilize the patient but also to minimize artifactual CVP elevation.

#### RADIOGRAPHY

Pericardial effusion enlarges the cardiac silhouette (Fig. 9-4). A massive amount of pericardial fluid causes the classic globoid-shaped heart shadow on both radiographic views. Smaller fluid volumes allow various cardiac contours to be identified, especially dorsally. Other findings associated with tamponade include pleural effusion, a distended caudal vena cava, hepatomegaly, and ascites. Pulmonary infiltrates of edema and distended pulmonary veins are seen ocasionally. Some heartbase tumors cause tracheal deviation or a soft-tissue mass effect. Metastatic lung lesions are common in dogs with hemangiosarcoma.

When used, fluoroscopy demonstrates diminished to absent motion of the cardiac shadow because of the fluid surrounding the heart. Angiocardiography is used only rarely now to evaluate patients with pericardial effusion and cardiac tumors; it typically reveals increased endocardialto-pericardial distance. Cardiac neoplasms can cause displacement of normal structures, filling defects, and vascular "blushing" (opacification of excessive, abnormal tumorassociated vessels). Pneumopericardiography has also been replaced by echocardiography. Pneumopericardiography uses carbon dioxide or air injected into the drained pericardial sac to outline the heart, but it is rarely used these days. Radiographs are taken from different orientations, but the left lateral and dorsoventral views are most helpful. These views allow the injected gas to outline the right atrial and heartbase areas, respectively, where tumors are most common.

#### **ELECTROCARDIOGRAPHY**

Although there are no pathognomonic electrocardiographic (ECG) findings, the following abnormalities are suggestive of pericardial effusion: small amplitude QRS complexes (<1 mV in dogs), electrical alternans, and ST segment elevation (epicardial injury current). Electrical alternans is a recurring alteration in the size of the QRS complex (or sometimes the T wave) with every other beat (Fig. 9-5). It results from the back-and-forth swinging motion of the heart within the pericardium. Electrical alternans is most likely to be seen in patients with large-volume pericardial effusion; it may be most evident at heart rates between 90 and 140/min and/or in the standing position. Sinus tachycardia is common with cardiac tamponade. Atrial or ventricular tachyarrhythmias may also occur.

#### **ECHOCARDIOGRAPHY**

Echocardiography is highly sensitive for detecting pericardial fluid, and it is the preferred diagnostic modality if radiographic changes are equivocal. Because fluid is sonolucent, pericardial effusion appears as an echo-free space between the bright parietal pericardium and the epicardium (Fig. 9-6). Abnormal cardiac wall motion and chamber shape and intrapericardial or intracardiac mass lesions can also be imaged. With large-volume pericardial effusion, the heart may appear to swing back and forth within the pericardial sac. Cardiac tamponade is manifested by diastolic compression/collapse of the right atrium and sometimes the

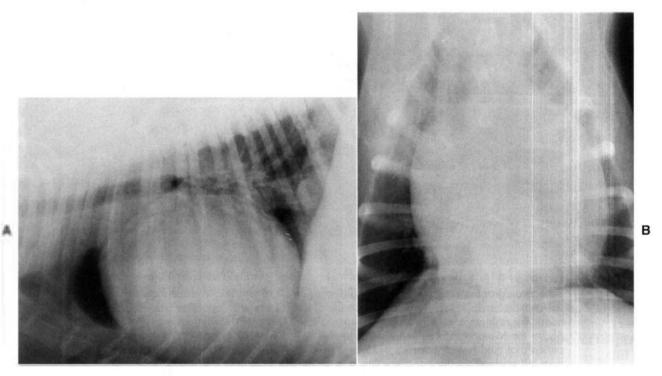

FIG 9-4
Lateral (A) and dorsoventral (B) radiographs from a mixed-breed dog with large pericardial effusion. Note globoid shape of cardiac silhouette and distended caudal vena cava (A).

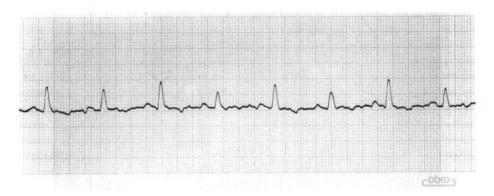

FIG 9-5

right ventricle (Fig. 9-7). It must be remembered that the volume of effusion is not the main determinant of hemodynamic compromise but rather the intrapericardial pressure. The RV and RA walls are often well visualized and may appear hyperechoic because of the surrounding fluid. Better visualization of the heartbase and mass lesions is generally obtained before pericardiocentesis is performed. Careful evaluation of all portions of the right atrium and auricle, right ventricle, ascending aorta, and pericardium itself is important to screen for neoplasia. The left cranial parasternal (and transesophageal) transducer positions are especially useful. Some mass lesions are difficult to visualize.

Mesothelioma may not cause discrete mass lesions and therefore may be indistinguishable from idiopathic pericardial effusion.

Sometimes pleural effusion, a markedly enlarged left atrium, a dilated coronary sinus, or persistent left cranial vena cava can be confused with pericardial effusion. Careful scanning from several positions helps in differentiating these conditions. Identification of the parietal pericardium in relation to the echo-free fluid helps differentiate pleural from pericardial effusion. Because the pericardium is a relatively strong ultrasound reflector, by progressively dampening the returning echo signals, pericardial echos are seen to be the

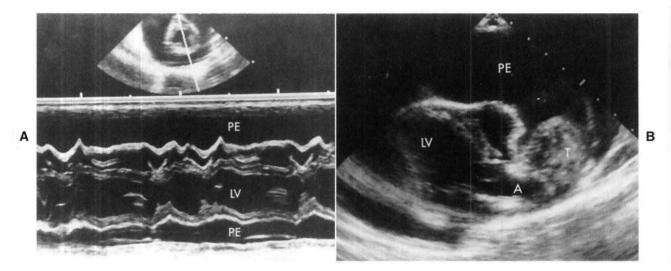

FIG 9-6

Echocardiographic examples of pericardial effusion. **A,** Short-axis M-mode view at mitral valve and chordal levels. Large echo-free (fluid) spaces are seen on either side of the heart; the right ventricular wall is clearly visualized. The small two-dimensional image above the M-mode shows the heart (transected by the M-mode cursor line) surrounded by pericardial fluid (which appears black on the image). **B,** Long-axis two-dimensional view from left parasternal position depicting a large heartbase tumor and pericardial effusion in a Schnauzer. *PE*, Pericardial effusion; *T,* tumor; *LV*, left ventricle; *A,* aorta.

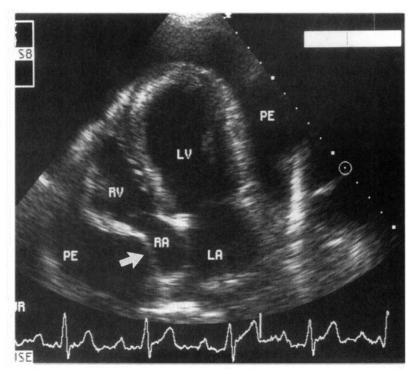

FIG 9-7

Diastolic compression of the right atrial wall (arrow) is evident in this left caudal four-chamber echocardiogram from a 3-year-old female Saint Bernard with cardiac tamponade. LA, Left atrium; LV, left ventricle; PE, pericardial effusion; RA, right atrium; RV, right ventricle.

last to disappear. Most pericardial fluid accumulates near the cardiac apex because the pericardium adheres more tightly to the heartbase; there is usually little fluid behind the left atrium. Furthermore, evidence of collapsed lung lobes or pleural folds can often be seen within pleural effusion.

#### **CLINICOPATHOLOGIC FINDINGS**

Hematologic and biochemical test results are generally nonspecific. The complete blood count (CBC) may suggest inflammation or infection. Cardiac HSA may be associated with a regenerative anemia, increased numbers of nucleated red blood cells and schistocytes, and thrombocytopenia. Mild hypoproteinemia is seen in some cases of pericardial effusion. Cardiac troponin concentration or enzyme activities may be increased as a result of ischemia or myocardial invasion; mild increases in liver enzyme activities and prerenal azotemia may occur secondary to heart failure. Pleural and peritoneal fluids in dogs and cats with cardiac tamponade are usually modified transudates.

Pericardiocentesis (discussed in the next section) usually yields a hemorrhagic effusion; occasionally the fluid is suppurative. Samples are submitted for cytologic analysis and saved for possible bacterial (or fungal) culture. Nevertheless, differentiation of neoplastic effusions from benign hemorrhagic pericarditis is usually impossible on the basis of cytology alone. Reactive mesothelial cells within the effusion may closely resemble neoplastic cells; furthermore, chemodectomas and HSAs may not shed cells into the effusion. Therefore identifying a mass lesion with echocardiography is helpful for diagnosis. The effusions in patients with lymphoma or MH typically are consistent with a modified transudate. Neoplastic cells usually are easily identified in dogs and cats with lymphoma and in dogs with MH. Many neoplastic (and other non-inflammatory) effusions have a pH of 7.0 or greater, whereas inflammatory effusions generally have lower pH. However, there appears to be too much overlap for pericardial pH to be used as a reliable discriminator. Pericardial fluid culture is performed if cytology and pH suggest an infectious or inflammatory cause. In some patients fungal titers (e.g., coccidioidomycosis) or other serologic tests are helpful. It is currently unclear whether analysis of pericardial fluid for cardiac troponins or other substances will allow better differentiation of the underlying etiology.

#### Treatment and Prognosis

It is important to differentiate cardiac tamponade from other causes of right-sided CHF because the treatment is very different. Positive inotropic drugs do not ameliorate the signs of tamponade; diuretics and vasodilators can further reduce cardiac output and exacerbate hypotension and shock. Pericardiocentesis (discussed in the next section) is the immediate treatment of choice, and it also provides diagnostic information. Most signs of CHF resolve after pericardial fluid is removed. A dose or two of a diuretic may be useful after pericardiocentesis in some animals. Pericardial effusions secondary to other diseases that cause CHF, congenital malformations, or hypoalbuminemia do not usually

cause tamponade and often resolve with management of the underlying condition.

Dogs with idiopathic pericardial effusion are initially treated conservatively by pericardiocentesis. After an infectious cause is ruled out by pericardial fluid culture or cytologic analysis, a glucocorticoid is often used (e.g., oral prednisone, 1 mg/kg/day, tapered over 2-4 weeks); however, its efficacy in preventing recurrent idiopathic pericardial effusion is unknown. Sometimes a 1- to 2-week course of a broad-spectrum antibiotic is used concurrently. Periodic reevaluation of these dogs by radiography or echocardiography is advised to detect recurrence. Apparent recovery occurs after one or two pericardial taps in about half of affected dogs. Cardiac tamponade recurs after a variable time span (days to years) in other cases. Some cases of recurrent effusion are caused by mesothelioma, MH, or other neoplasia, which may become evident on repeated echocardiographic exam.

Recurrent effusion that does not respond to repeated pericardiocenteses and antiinflammatory therapy is usually treated by subtotal pericardiectomy. Removal of the pericardium ventral to the phrenic nerves allows pericardial fluid drainage to the larger absorptive surface of the pleural space. The less invasive technique of thoracoscopic partial pericardiectomy has also been used successfully to treat idiopathic and some cases of neoplastic pericardial effusion; biopsy samples of the mass or masses (if identified) can be obtained through thoracoscopy. Lateral and subxiphoid approaches have been described. Percutaneous balloon pericardiotomy also appears to be an effective and even less invasive option for some cases. This procedure is performed under general anesthesia with fluoroscopic guidance. It involves placing a percutaneous sheath introducer through the chest wall into the pericardial space, then inserting a large balloon dilation catheter. The sheath is adjusted so that the balloon can be positioned across the pericardial membrane; as the balloon is inflated, it stretches the hole in the parietal pericardium. There is some concern that adhesions developing around a small pericardiotomy opening may result in fluid reaccumulation or increased risk of constrictive pericarditis.

Neoplastic pericardial effusions are also initially drained to relieve cardiac tamponade. Therapy may involve attempted surgical resection (depending on tumor size and location) or surgical biopsy, a trial of chemotherapy (based on biopsy or clinicopathologic findings), or conservative therapy until episodes of cardiac tamponade become unmanageable. Surgical resection of HSA is often not possible because of the size and extent of the tumor. Small tumors involving only the tip of the right auricle have been successfully removed; use of a pericardial patch graft may allow resection of larger masses involving the lateral RA wall. However, auriculectomy alone rarely results in prolonged long-term survival. Partial pericardiectomy may prevent the recurrence of tamponade. The increased potential for tumor dissemination throughout the thoracic cavity does not appear to affect survival time, compared with pericardiocentesis alone, in dogs with HSA or mesothelioma. The prognosis in dogs with RA HSA treated with surgery alone or in those in which treatment is declined by the owners is poor (median survival of 2-3 weeks); most dogs with atrial HSA have objective responses to multiagent chemotherapy (VAC protocol) and survival times of 4 to 8 months. Survival time in dogs with mesothelioma may be slightly longer than in those with HSA, but the overall prognosis is poor.

Heartbase tumors (e.g., chemodectoma) tend to be slow growing and locally invasive and have a low metastatic potential. Partial pericardiectomy may prolong survival for years. Percutaneous balloon pericardiotomy may also be an effective palliative procedure. Because of local invasion, complete surgical resection is rarely possible; attempts at aggressive resection often result in severe bleeding and death. However, small, well-defined masses may be completely resectable. Surgical biopsy is indicated if chemotherapy is contemplated. Effusion secondary to myocardial lymphoma, usually easily diagnosed cytologically, often responds to pericardiocentesis and chemotherapy.

Infectious pericarditis should be treated aggressively with appropriate antimicrobial drugs, as determined by microbial culture and sensitivity testing. Surgical therapy is likely to be more effective than continuous drainage with an indwelling pericardial catheter, and it also allows removal of penetrating foreign bodies. The prognosis is guarded. Even with successful elimination of infection, epicardial and pericardial fibrin deposition may lead to constrictive pericardial disease.

Pure hemorrhage into the pericardial space, whether the result of trauma, rupture of the left atrium, or a systemic coagulopathy, should be removed if signs of cardiac tamponade exist. Only enough blood to control signs of tamponade should be removed because continued drainage may predispose to further bleeding. The remaining blood is usually resorbed through the pericardium (autotransfusion). Surgery may be needed to stop continued bleeding or remove large clots. Dogs that survive an initial episode of intrapericardial bleeding from rupture of the left atrium still have a guarded to poor prognosis because of recurrent tearing of the left atrium. Animals with intrapericardial hemorrhage of unclear cause should be evaluated for a coagulation disorder. When trauma-induced intrapericardial hemorrhage persists in an animal with normal hemostasis, surgical exploration is indicated.

#### Complications

Complications of diseases causing pericardial effusion relate to (1) sequelae of the fluid accumulation itself (e.g., cardiac tamponade and compression of surrounding structures [lung, esophagus, trachea]), (2) immediate effects of associated inflammatory processes (e.g., arrhythmias, local and systemic effects of infectious agents, further fluid formation), (3) pericardial fibrosis and subsequent constrictive pericarditis, (4) sequelae of neoplastic processes (e.g., further bleeding, metastases, local invasion and obstruction, seeding of the pleura, loss of function), and (5) complications of pericardiocentesis (discussed in the next section). Overly aggressive surgical attempts to remove cardiac tumors or the

entire pericardial sac can be fatal, and partial pericardiectomy may enhance intrathoracic dissemination of certain tumors such as mesothelioma and carcinoma.

#### **PERICARDIOCENTESIS**

Pericardiocentesis should be done immediately in animals with cardiac tamponade. Administration of diuretics or vasodilators without pericardiocentesis may cause further hypotension and cardiogenic shock. Pericardiocentesis is a relatively safe procedure when performed carefully. Removal of even a small volume of pericardial fluid can markedly decrease intrapericardial pressure in animals with tamponade.

Pericardiocentesis is usually done from the right side to minimize the risk of trauma to the lung (via the cardiac notch) and major coronary vessels (located mostly on the left). The need for sedation depends on the clinical status and temperament of the animal. The animal is usually placed in left lateral or sternal recumbency for more secure restraint, especially if the animal is weak or excitable. Sometimes needle pericardiocentesis can be successfully performed on the standing animal, but the risk of injury increases if the patient suddenly moves. An elevated echocardiography table with a large cutout can also be used with good success; the animal is placed in right lateral recumbency, and the tap is performed from underneath. An advantage to this method is that fluid moves to the right side with gravity; however, if adequate space is not available for wide sterile skin preparation or needle/catheter manipulation, this approach is not advised. Echo guidance can be used but is not necessary unless the effusion is of very small volume or appears compartmentalized.

A variety of equipment can be used for pericardiocentesis. A butterfly needle/catheter (19- to 21-gauge) or appropriately long hypodermic or spinal needle attached to extension tubing is adequate in emergency situations. An over-theneedle catheter system is a safer alternative because it reduces the risk of cardiopulmonary laceration during fluid aspiration. The catheter is chosen according to patient size (e.g., 12- to 16-gauge, 4- to 6-inch long catheter for large dogs, down to 18- to 20-gauge, 11/2- to 2-inch long catheter for small dogs or cats). A few extra small side holes may be smoothly cut (with sterile scissors) near the tip of larger catheters to increase fluid removal rate. During initial catheter placement the extension tubing is attached to the needle stylet. After the catheter is advanced into the pericardial space, the extension tubing is reattached directly to the catheter. With all methods, a three-way stopcock is placed between the tubing and a collection syringe.

An ECG monitor should be in place during pericardiocentesis because needle/catheter contact with the heart commonly induces ventricular arrhythmias. The skin is shaved over a wide area of the right precordium (from about the third to seventh intercostal spaces and from sternum to costochondral junction) and surgically prepared. Sterile gloves and aseptic technique are used for the procedure. The puncture site is located by palpating to identify the point at which the cardiac impulse feels strongest (usually between the fourth and sixth ribs just lateral to the sternum). Local anesthesia is necessary when using large catheters and recommended for needle pericardiocentesis. Lidocaine (2%) is infiltrated with sterile technique at the skin puncture site, into underlying intercostal muscles, and into the pleura. A small stab incision is made in the skin to allow catheter entry.

Intercostal vessels are located just caudal to each rib and must be avoided when entering the chest. Once the needle has penetrated the skin, the operator's assistant should apply gentle negative pressure to the attached syringe as the operator slowly advances the needle toward the heart. It is sometimes helpful to aim the tip of the needle toward the animal's opposite shoulder. The tubing is observed so that fluid will be seen as soon as it is aspirated. Pleural fluid (usually straw colored) may enter the tubing first and is drained as much as possible. The pericardium creates increased resistance to needle advancement and may produce a subtle scratching sensation. Gentle pressure is used to advance the needle through the pericardium. A loss of resistance may be noted with needle penetration, and fluid aspirated into the tubing usually appears dark red. If the needle comes into contact with the heart, a marked scratching or tapping sensation is usually felt, the needle may move with the heartbeat, and ventricular premature complexes are often provoked. The needle should be retracted slightly if cardiac contact occurs. It is important to avoid excessive needle motion within the chest. When a catheter system is used, after the needle/stylet is well within the pericardial space, the catheter is advanced, the stylet removed, and the extension tubing attached to the catheter. Initial fluid samples are saved for cytologic exam and possible culture, and then as much fluid as possible is aspirated.

Pericardial effusion usually appears quite hemorrhagic. It can be distressing to see dark, bloody fluid being aspirated from near the heart, but pericardial fluid can be differentiated from intracardiac blood in several ways. Unless the fluid is caused by very recent pericardial hemorrhage, it will not clot. (A few drops can be placed on the table or into a serum tube to check.) The PCV of pericardial fluid is usually much lower than that of peripheral blood (except in some dogs with HSA); also, the supernatant is xanthochromic (yellow tinged) when spun in a hematocrit tube. As the pericardial fluid is drained, the animal's ECG complexes increase in amplitude, tachycardia diminishes, and the patient often takes a deep breath and appears more comfortable.

#### Complications

Complications of pericardiocentesis include (1) cardiac injury or puncture causing arrhythmias (the most common complication, although usually self-limiting when the needle is withdrawn), (2) lung laceration causing pneumothorax and/or hemorrhage, (3) coronary artery laceration with myocardial infarction or further bleeding into the pericardial space, and (4) dissemination of infection or neoplastic cells into the pleural space.

#### CONSTRICTIVE PERICARDIAL DISEASE

#### **Etiology and Pathophysiology**

Constrictive pericardial disease is diagnosed occasionally in dogs but only rarely in cats. This condition occurs when thickening and scarring of the visceral and/or parietal pericardium restrict ventricular diastolic expansion and prevent normal cardiac filling. Both ventricles are affected. Usually the entire pericardium is involved symmetrically. Fusion of parietal and visceral pericardial layers obliterates the pericardial space in some cases. In others the visceral layer (epicardium) alone is involved. A small amount of pericardial effusion (constrictive-effusive pericarditis) may be present.

Increased fibrous connective tissue and variable amounts of inflammatory and reactive pericardial infiltrates are seen on histopathologic exam. Although the etiology of constrictive pericardial disease is often unknown, acute inflammation with fibrin deposition and possibly varying degrees of pericardial effusion are thought to precede its development. Some cases in dogs are attributable to recurrent idiopathic hemorrhagic effusion, infectious pericarditis (resulting from actinomycosis, mycobacteriosis, coccidioidomycosis), a metallic foreign body in the pericardium, tumors, and idiopathic osseous metaplasia and/or fibrosis of the pericardium.

In advanced constrictive pericardial disease, ventricular filling is limited essentially to early diastole, before ventricular expansion is abruptly curtailed. Any further ventricular filling is accomplished only at high venous pressures. Compromised filling reduces cardiac output, and compensatory mechanisms of heart failure cause fluid retention, tachycardia, and vasoconstriction.

#### **Clinical Features**

Middle-aged, large- to medium-breed dogs are most often affected. Males and German Shepherd Dogs may be at higher risk. Some dogs have a history of pericardial effusion. Clinical signs of right-sided CHF predominate. Abdominal distention (ascites), tachypnea or labored breathing, tiring, syncope, weakness, and weight loss are common complaints. These signs may develop over weeks to months. Ascites and jugular venous distention are the most consistent clinical findings, as in dogs with cardiac tamponade. Weakened femoral pulses and muffled heart sounds are also typical. A diastolic pericardial knock sound, resulting from abrupt deceleration of ventricular filling in early diastole, has been described but is not often identified in dogs. A systolic murmur or click, probably caused by valvular disease rather than the pericardial pathology, or a diastolic gallop sound may be heard.

#### **Diagnosis**

The diagnosis of constrictive pericardial disease may be difficult. Typical radiographic findings include mild to moderate cardiomegaly, pleural effusion, and caudal vena cava distention. Reduced cardiac motion may be evident on fluo-

roscopy. Echocardiographic changes in dogs with constrictive pericardial disease may be subtle; suggestive findings include diastolic flattening of the left ventricular freewall and abnormal septal motion. The pericardium may appear thickened and intensely echogenic, but differentiating this from normal pericardial echogenicity may be impossible. Possible ECG abnormalities include sinus tachycardia, P-wave prolongation, and small QRS complexes.

A CVP >15 mm Hg is common. Intracardiac hemodynamic measurements are most useful diagnostically. In addition to high mean atrial and diastolic ventricular pressures, the atrial pressure waveform shows a prominent y descent (during ventricular relaxation). This is in contrast to cardiac tamponade, wherein the y descent is diminished. During tamponade, ventricular diastolic expansion immediately raises intrapericardial pressure and impairs caval flow into the right atrium, thus preventing the normal early diastolic decrease in CVP (y descent), although flow into the right atrium (and x descent on atrial waveform) continues during ventricular contraction. With constrictive pericardial disease, filling pressure is low only in early diastole (during the time of y descent). Another classic finding with constrictive pericardial disease is an early diastolic dip in ventricular pressure, followed by a mid-diastolic plateau, but this is not consistently seen in dogs. Results of angiocardiography may be normal, or they may show atrial and vena caval enlargement with increased endocardial-pericardial distance.

#### Treatment and Prognosis

Therapy for constrictive pericardial disease consists of surgical pericardiectomy. This is more successful when only the parietal pericardium is involved. Constrictive pericardial disease involving the visceral layer requires epicardial stripping. This procedure increases the surgical difficulty and associated complications. Pulmonary thrombosis is reportedly a common postoperative complication and can be lifethreatening. Tachyarrhythmias are another complication of surgery. In the postoperative period, a diuretic and possibly an angiotensin-converting enzyme inhibitor (ACEJ) may be helpful. Positive inotropic and vasodilating drugs are not usually indicated. Constrictive pericardial disease is progressive and, without successful surgical intervention, ultimately fatal.

#### CARDIAC TUMORS

#### **Etiology and Pathophysiology**

Echocardiography has made the antemortem diagnosis of cardiac tumors more common, although the overall prevalence of such neoplasms is low. Some cardiac tumors cause severe clinical signs, whereas others are diagnosed fortuitously. Dogs with cardiac tumors tend to be middle-aged and older. More than 85% of affected dogs are between 7 and 15 years of age; however, very old dogs (>15 years) have a surprisingly low prevalence. Reproductive status influences the relative risk for cardiac tumors in dogs, despite a similar frequency of occurrence in males and females overall. Neutered dogs have a greater relative risk, especially spayed females, which have a risk that is four to five times greater compared with that of intact females. Intact and neutered males also have greater risk than intact females. Certain breeds of dog have a higher prevalence of cardiac tumor compared with the general population (Table 9-1). The age distribution of cats with cardiac tumors is different from that of dogs; about 28% are 7 years old or younger. It is unknown whether reproductive status affects relative risk for cardiac tumors in cats.

The most common cardiac tumor in dogs is HSA. Most are located in the right atrium and/or right auricle; some also infiltrate the ventricular wall. HSAs usually are associated with hemorrhagic pericardial effusion and cardiac tampon-

ade (see p. 158). Metastases are common by the time of diagnosis. Golden Retrievers, German Shepherd Dogs, Afghan Hounds, Cocker Spaniels, English Setters, and Labrador Retrievers, among others, are at higher risk for this tumor.

Masses at the heartbase are the second most frequently reported cardiac tumor in dogs. They are usually neoplasms of the chemoreceptor aortic bodies (chemodectoma, aortic body tumors); ectopic thyroid or parathyroid, or mixed-cell-type tumors also occur here. Heartbase tumors tend to be locally invasive around the root of the aorta and surrounding structures; metastases to other organs occur rarely. Chemodectomas are reported more frequently in brachycephalic dogs (specifically Boxers, Boston Terriers, and Bull-dogs) but affect individuals of other breeds as well. Clinical signs associated with heartbase tumors are usually related to pericardial effusion and cardiac tamponade.

Mesothelioma occurs sporadically; there may be geographical variation in its prevalence. Other primary tumors involving the heart are rare in dogs but include myxoma, various types of sarcoma, and other neoplasms. Most cases involve right-heart structures. Metastatic tumors, including lymphoma, other sarcomas, and various carcinomas, may involve the heart as well. MH may involve the heart or pericardium; most affected dogs are either Golden Retrievers, Labrador Retrievers, Rottweilers, or Greyhounds. Mild pericardial effusion, without overt signs of cardiac tamponade, co-exists with pleural and abdominal effusion.

Lymphoma is the most common cardiac tumor in cats. Various (mostly metastatic) carcinomas are the next most common cardiac neoplasms in cats. HSA is uncommon; other tumors (such as aortic body tumor, fibrosarcoma, rhabdomyosarcoma) are reported only rarely in cats.

Cardiac tumors cause several pathophysiologic abnormalities, depending on their location and size. Ultimately, the patient's clinical signs can be referred to one or a combination of these. Many tumors impede cardiac filling by causing pericardial effusion and cardiac tamponade (discussed earlier). An intrapericardial mass can itself externally compress the heart as well as cause pericardial effusion. Alternatively, a tumor that grows in an intracardiac location can physically obstruct cardiac inflow or outflow. Myocardial tumor infiltration or secondary ischemia can disrupt the cardiac rhythm and impair contractility. If the tumor is small or has not yet markedly impaired cardiac function, clinical signs may be absent.

#### **Clinical Features**

Signs of right-sided CHF result from blood flow obstruction within the right atrium or ventricle or from cardiac tamponade. Syncope, weakness associated with exertion, and other low output signs also result from cardiac tamponade, blood flow obstruction, arrhythmias, or impaired myocardial function secondary to cardiac tumors. Tachyarrhythmias of any type may also occur; intracardiac conduction disturbances sometimes result from tumor infiltration. Lethargy or collapse may relate to bleeding tumors (e.g., HSA) present in extracardiac locations as well.

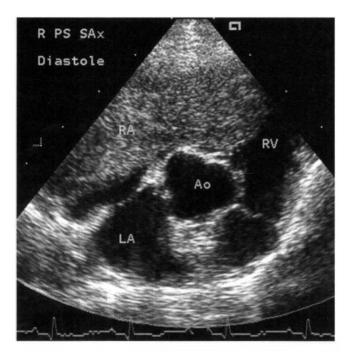

Auscultation findings vary. Arrhythmias or muffled heart sounds (if large pericardial effusion is present) are common. Occasionally a murmur is caused by neoplastic obstruction of intracardiac blood flow, but murmurs associated with unrelated disease (e.g., degenerative mitral regurgitation) are more common. Auscultation findings may be normal.

#### Diagnosis

Radiographic findings are also quite variable. The cardiac silhouette may be normal or show an unusual bulge, a mass effect adjacent to the heart, or a globoid cardiac silhouette compatible with pericardial effusion. Intrapericardial masses are obscured by pericardial effusion. Other radiographic findings that occur secondary to impaired cardiac filling include pleural effusion, evidence of pulmonary edema, widening of the caudal vena cava (and/or pulmonary veins), hepatomegaly, and ascites. Dorsal deviation of the trachea and increased perihilar opacity are seen in some dogs with heartbase tumors. Evidence of pulmonary metastases is found with some primary or secondary (metastatic) cardiac neoplasms.

ECG findings sometimes show abnormalities suggesting the location and sequelae of the underlying disease, such as chamber enlargement, pericardial effusion, and various arrhythmias. Echocardiography can depict cardiac masses and determine the presence or absence of pericardial effusion as well as secondary changes in cardiac chamber size, shape, and ventricular function. Doppler techniques allow assessment of associated blood flow abnormalities. Heartbase tumors that extend into the pericardial space are easier to see when there is pericardial effusion, just as intracardiac masses are accentuated by the echolucent intracardiac blood surrounding them (Fig. 9-8). The left cranial parasternal transducer position may be especially useful in evaluating the ascending aorta, right auricle, and surrounding structures. Echocardiographic assessment of the tumor's location, size, attachment (pedunculated or broad based), and extent (superficial or deeply invading adjacent myocardium) may help in determining whether surgical resection or biopsy is possible. Visualizing a suspected mass lesion in more than one echocardiographic plane helps verify it and prevent the misinterpretation of artifacts.

Pericardial fluid analysis is recommended, although definitive diagnosis of neoplasia cannot usually be made on the basis of cytologic findings alone (see p. 163). Cardiac lymphoma or MH is more likely to be diagnosed on pericardial fluid cytology. Nevertheless, visualization of a cardiac mass using echocardiography, computed tomography, pneumopericardiography, angiography, or another modality is usually necessary for diagnosis. Hematologic and serum biochemical tests are generally nonspecific in dogs and cats with cardiac tumors. Cardiac enzyme activities or circulation troponin concentrations may be high because of ischemia or myocardial invasion; mild increases in serum alanine aminotransferase activity and azotemia may occur with CHF. HSA is often associated with a regenerative anemia, increased number of nucleated red blood cells and schistocytes, leuko-

cytosis, and thrombocytopenia. If present, pleural and peritoneal fluids are usually modified transudates.

#### **Treatment and Prognosis**

Unfortunately, there are few good long-term options in most patients with a heart tumor. Cardiac tamponade is managed when it occurs (see p. 163). Conservative therapy (pericardiocentesis as needed, possibly with glucocorticoid administration to decrease inflammation) is used in some animals. Partial pericardiectomy or pericardiotomy may be helpful in animals with recurrent tamponade.

Surgical tumor resection may be possible depending on the location, size, and invasiveness of the mass. Tumors involving only the tip of the right auricular appendage or a pedunculated mass in a surgically accessible location are more likely to be resectable. Intracardiac masses within the right side of the heart might be reached using venous inflow occlusion techniques and rapid cardiotomy; however, surgical access to lesions on the left side of the heart and large or medially attached masses in the right heart generally requires cardiopulmonary bypass.

Surgical biopsy of a nonresectable mass may be helpful if chemotherapy is being contemplated. Although many cardiac tumors appear to be fairly unresponsive to chemotherapy, some are treated with short-term success. Some cardiac hemangiosarcomas respond to vincristine, doxorubicin, and cyclophosphamide combination chemotherapy for 4 to 8 months. Lymphoma and MH should be treated using standard protocols.

#### GENERAL CONSIDERATIONS

#### **HEARTWORM LIFE CYCLE**

The heartworm (Dirofilaria immitis) is transmitted by various species of mosquitoes, which act as its obligate intermediate host. A mosquito initially ingests the microfilariae, or first-stage larvae ( $L_1$ ), which circulate in the blood of an infected host animal. The  $L_1$  develops into an  $L_2$  and then enters the infective  $L_3$  stage within the mosquito over a period of approximately 2 to 2.5 weeks. Infective larvae enter

the new host when the mosquito takes another blood meal.  $L_3$  larvae migrate subcutaneously within the new host, molting into an  $L_4$  stage within 9 to 12 days, and then entering the  $L_5$  stage. The juvenile  $L_5$  worms enter the vasculature about 100 days after infection, where they migrate preferentially to the peripheral pulmonary arteries of the caudal lung lobes. It takes at least 5 and usually more than 6 months before these worms develop into adults, at which time gravid females release microfilariae and the infection becomes patent.

Microfilariae passed to another animal by blood transfusion or across the placenta do not develop into adult worms because the mosquito host is required to complete the parasite's life cycle. Therefore puppies younger than 6 months of age that have circulating microfilariae most likely received them transplacentally and do not have patent heartworm disease (HWD).

HWD is widespread throughout the United States, especially along the eastern and gulf coasts and in the Mississippi River valley. Sporadic cases occur in other areas of the country and Canada; the disease is prevalent in other regions of the world as well. Heartworm transmission is limited by climate. An average daily temperature of >64° F for about a month is needed for the  $L_1$  larvae to mature within a mosquito to the infective stage. Heartworm transmission peaks during July and August in temperate regions of the Northern Hemisphere.

Dogs and other canids are the preferred host species. Although cats are also affected by HWD, they are more resistant to infection than dogs. The overall prevalence of heartworm disease in cats is thought to be 5% to 20% of that in dogs in the same geographic area. Reported prevalences range from 0% to >16%. In the United States, cases have been identified in most of the midwest and eastern states and in California.

#### **TESTS FOR HEARTWORM DISEASE** Serologic Tests

**Antigen tests.** Adult heartworm antigen (Ag) tests are recommended as the main screening test for HWD in dogs.

Currently available Ag test kits are highly accurate. Because monthly heartworm preventive drugs promote occult infections by virtually eliminating circulating microfilariae, Ag testing provides higher overall sensitivity for diagnosing HWD. Circulating Ag is usually detectable by about 6.5 to 7 months after infection but not sooner than 5 months. There is no reason to test puppies younger than 7 months. Testing of adults is recommended at about 7 months after the preceding transmission season. Depending on the climate, monthly heartworm prophylaxis may have been started (or continued) before that time.

Commercially available test kits are immunoassays that detect circulating heartworm Ag from the adult female reproductive tract. Most are enzyme-linked immunosorbent assays (ELISAs), although hemagglutination and immunochromatographic test methods also are available. These tests are generally very specific and have a good sensitivity. Positive results are consistently obtained when at least three female worms 7 to 8 months or older are present. Most kits do not detect infections less than 5 months old, and male worms are not detected. Most serum/plasma kits often can identify infections with one live female worm. Microwellformat ELISA tests in general are slightly more sensitive than the rapid assay, membrane-format tests. Of the latter the SNAP test (IDEXX Laboratories, Westbrook, Maine) reportedly is more sensitive for detecting infections with 1 or 2 female worms. A weak positive or ambiguous test result may be rechecked using a different test kit or repeated after a short time with the same type of kit; microfilaria testing and chest radiographs can also help determine whether infection is present. A false-positive Ag test result can usually be traced to a technical error. False-negative results may occur with a low worm burden, immature female worms only, male unisex infection, or a cold test kit. Because the adult worm burden is low in cats and there is greater probability of male unisex infections, false-negative test results are more likely in this species.

Antibody tests. Heartworm antibody tests are marketed for cats. The ELISA antibody (Ab) tests use either recombinant Ag or heartworm Ag extracted and purified from male and female worms. These tests are used to screen for feline heartworm disease. The Ab tests have minimal to no cross-reactivity with gastrointestinal (GI) parasitic infections. Ab tests provide greater sensitivity than Ag tests because larvae of either sex can provoke a host immune response. The specificity of the Ab tests for HWD is of some concern, however. Serum Ab to both immature and adult worms is detected as early as 60 days after infection, and some immature heartworm larvae never develop into adults. Therefore a positive Ab test indicates exposure to migrating larvae as well as adults, not the presence of adult heartworms specifically. When the Ab test is positive, other evidence also should be sought to support a diagnosis of HWD. This can include a positive heartworm Ag test or findings consistent with HWD on thoracic radiography and echocardiography. The concentration of Ab does not appear to correlate well with an individual cat's worm burden, nor with the severity

of clinical disease or radiographic signs. High Ab titers are associated with heartworm death as well as heavy infection. It is unclear how long circulating Ab remain after elimination of heartworm infection.

False negative Ab tests also occur fairly frequently (in up to approximately 14% of cases). These are usually related to infection with a single worm and are a matter of concern because the feline worm burden is often low. Therefore a negative heartworm Ab test suggests one of the following: (1) the cat does not have heartworm infection, (2) the cat has an infection less than 60 days old, or (3) the cat produced a concentration of IgG Ab against the Ag used in making the test that is too low to be detected. When clinical findings suggest HWD but the Ab test is negative, serological testing should be repeated using a different Ab test and a heartworm Ag test. Chest radiographs and an echocardiogram are also recommended. The Ab test may also be repeated in a few months.

#### Microfilaria Identification

Tests for circulating microfilariae are no longer recommended for routine heartworm screening. They are useful in identifying patients that are reservoirs of infection and to assess whether high numbers of microfilariae are present before a monthly preventive drug is administered. Microfilaria testing is mandatory if diethylcarbamazine (DEC) is to be used as a heartworm preventive. The macrocyclic lactone preventive drugs, administered monthly, reduce and eliminate microfilaremia by impairing the reproductive function of female and possibly also male worms. Most dogs become amicrofilaremic by the sixth monthly dose with these drugs. However, up to 90% of heartworm-positive dogs that are not treated monthly with a macrolide have circulating microfilariae. The remaining so-called occult infections, in which there are no circulating microfilariae, can result from an immune response that destroys the microfilariae within the lung (true occult infection), unisex infection, sterile adult heartworms, or the presence of only immature worms (prepatent infection). Occult infections are frequently associated with severe signs of disease. Low numbers of microfilariae and diurnal variations in the number of circulating microfilariae in peripheral blood can also cause false-negative microfilaria test results. Circulating microfilariae are rarely found in cats with HWD.

Microfilaria concentration tests that use at least 1 ml of blood are recommended for detecting circulating microfilariae. The nonconcentration tests are more likely to miss low numbers of microfilariae, although they do allow observation of mirofilarial motility. *Dirofilaria* have a stationary rather than a migratory movement pattern. Nonconcentration tests include examination of a fresh wet blood smear or the buffy coat of a spun hematocrit tube.

Concentration tests are done using either a millipore filter or the modified Knott's centrifugation technique. Both techniques lyse the red blood cells and fix any existing microfilariae. The modified Knott test is preferred for measuring larval body size and differentiating *D. immitis* from non-

TABLE 10-1

Morphologic Differentiation of Microfilaria

SMEAR	DIROFILARIA IMMITIS	DIPETALONEMA RECONDITUM
Fresh smear	Few to large numbers	Usually small numbers
	Undulate in one place	Move across field
Stained	Straight body	Curved body
smear*	Straight tail	Posterior extremity hook ("button hook" tail); inconsistent finding
	Tapered head >290 μm long >6 μm wide	Blunt head <275-280 μm long <6 μm wide

<sup>\*</sup>Size criteria given for lysate prepared using 2% formalin (modified Knott's test); microfilariae tend to be smaller with lysate of filter tests. Width and morphology are the best discriminating factors.

pathogenic filarial larvae, such as *Acanthocheilonema* (formerly *Dipetalonema*) *reconditum* (Table 10-1). An occasional false-positive microfilaria test result occurs in animals with microfilariae but no live adult heartworms.

#### HEARTWORM DISEASE IN DOGS

#### Pathophysiology

Heartworm disease is an important cause of pulmonary hypertension (cor pulmonale) in regions where the disease is endemic. Increased pulmonary vascular resistance raises pulmonary arterial pressure according to the relationship: cardiac output =  $\Delta$  pressure/resistance. The presence of adult worms in the pulmonary arteries provokes reactive vascular lesions sthat reduce vascular compliance and lumen size. Within days after young heartworms enter the pulmonary arteries, pathologic changes begin in these vessels. The hostparasite interaction is thought to be more important than the worm number alone in the development of clinical signs, although a large worm burden may be associated with severe disease. The pathogenesis of HWD may be modulated by obligate intracellular bacteria (genus Wolbachia) that are harbored by the worms. This may involve bacterial endotoxins as well as the host immune response to a major Wolbachia surface protein, which is thought to contribute to pulmonary and renal inflammation. Little correlation has been found between pulmonary vascular resistance and the number of worms present. A low worm burden can produce serious lung injury and a greater rise in pulmonary vascular resistance if the cardiac output is high. The increase in pulmonary blood flow associated with exercise exacerbates the pulmonary vascular pathology.

Villous myointimal proliferation of the pulmonary arteries containing heartworms is the characteristic lesion.

The heartworm-induced changes begin with endothelial cell swelling, widening of intercellular junctions, increased endothelial permeability, and periarterial edema. Endothelial sloughing leads to the adhesion of activated white blood cells and platelets. Various trophic factors stimulate smooth muscle cell migration and proliferation within the media and into the intima. Villous proliferations consist of smooth muscle and collagen with an endothelium-like covering. These proliferative changes of the intima occur 3 to 4 weeks after adult worms arrive. They cause luminal narrowing of the smaller pulmonary arteries and also induce further endothelial damage and more proliferative lesions. Hypersensitivity pneumonitis may contribute to parenchymal lung lesions. Endothelial damage promotes thrombosis as well as a perivascular tissue reaction and periarterial edema. Interstitial and alveolar infiltrates may become radiographically apparent; partial lung consolidation develops in some animals. Hypoxic vasoconstriction can also play a role in the vascular changes that increase pulmonary vascular resistance and consequently cause pulmonary hypertension. Dead worms stimulate greater host response and worsen the pulmonary disease. Worm fragments and thrombi cause embolization and a more intense reaction, which eventually leads to fibrosis.

The worm distribution, and accompanying villous proliferation, is most severe in the caudal and accessory lobar arteries. Affected pulmonary arteries lose their normal tapered peripheral branching appearance and appear blunted or pruned. Aneurysmal dilation and peripheral occlusion may occur. The vessels become tortuous and proximally dilated as the increased pulmonary vascular resistance demands higher perfusion pressures.

Right ventricular dilation and concentric hypertrophy are the responses to a chronic requirement for increased systolic pressure. Chronic pulmonary hypertension can lead to right ventricular (RV) myocardial failure, increased RV diastolic pressure, and signs of right-sided congestive heart failure (CHF), especially in conjunction with secondary tricuspid insufficiency. Cardiac output progressively declines as the RV fails. When cardiac output becomes inadequate during exercise, exertional dyspnea, fatigue, and syncope may occur.

Chronic hepatic congestion secondary to HWD may lead to permanent liver damage and cirrhosis. Circulating immune complexes or possibly microfilarial antigens provoke glomerulonephritis. Renal amyloidosis has also been associated with HWD in dogs in rare cases. Occasionally, aberrant worms can cause embolization of the brain, eye, or other systemic arteries.

Although the caudal pulmonary arteries are the preferred site, worm migration to the caudal vena cava is associated with heavy worm burdens. A massive number of worms can cause mechanical occlusion of the RV outflow tract, pulmonary arteries, tricuspid valve region, or venae cavae. This is known as the *caval syndrome*. Cases of systemic arterial migration causing hindlimb lameness, paresthesia, and ischemic necrosis are sporadically described.

## PULMONARY HYPERTENSION WITHOUT HEARTWORM DISEASE

A number of diseases besides HWD are associated with pulmonary hypertension in dogs, including hypoxic pulmonary disease and vascular obstructive disease (e.g., pulmonary thromboembolism). Vascular obstruction reduces total cross-sectional pulmonary vascular area by mechanically obstructing vessels and provoking local hypoxic pulmonary vasoconstriction as well as other reactive changes. Associated pulmonary parenchymal disease can contribute to reduced vascular area.

Chronic elevations in pulmonary venous pressure (as from mitral regurgitation) may increase pulmonary artery pressure but usually only mildly to moderately. Pulmonary edema or congestion associated with high venous pressure can contribute to increased pulmonary vascular resistance by reducing lung compliance and increasing resistance to air flow. Pulmonary overcirculation caused by a congenital cardiac shunt can cause vascular injury and pulmonary arterial remodeling leading to high vascular resistance, pulmonary hypertension and shunt reversal (Eisenmenger's physiology; see p. 109).

#### **Clinical Features**

There is no specific age or breed predilection for HWD in dogs. Although most affected dogs are between 4 and 8 years old, HWD is also diagnosed in dogs <1 year (but >6 months) of age as well as in geriatric animals. Males are affected two to four times as often as females. Large-breed dogs and those living mainly outdoors are at much greater risk of infection than small-breed and indoor dogs. The length of the haircoat does not appear to affect infection risk.

Dogs diagnosed by a positive routine screening test are often asymptomatic. Dogs with occult disease and those not routinely tested are more likely to have advanced pulmonary arterial disease and clinical signs. Dogs with clinical disease often have a history of fatigue, shortness of breath or exertional dyspnea, syncope, cough, hemoptysis, weight loss, or signs of right-sided CHF. A change in or loss of the dog's bark has sometimes been reported.

Physical examination findings may be normal in patients with early or mild disease. Severe disease is frequently associated with poor body condition, tachypnea or dyspnea, jugular vein distention or pulsations, ascites, or other evidence of right-sided CHF. Increased or abnormal lung sounds (wheezes and crackles), a loud and often split second heart sound (S2), an ejection click or murmur at the left heartbase, a murmur of tricuspid insufficiency, or cardiac arrhythmias are variably heard on auscultation. Severe pulmonary arterial disease and thromboembolism can lead to disseminated intravascular coagulation (DIC), thrombocytopenia, epistaxis, and possibly hemoglobinuria. Hemoglobinuria is also associated with caval syndrome. Aberrant worm migration to the central nervous system, eye, femoral arteries, subcutis, peritoneal cavity, and other sites occurs occasionally and causes related signs.

#### **Diagnosis**

#### RADIOGRAPHY

Radiographic findings are often normal early in the disease, although marked changes can develop rapidly in dogs with heavy worm burdens. Characteristic findings include RV enlargement, a pulmonary trunk bulge, and centrally enlarged and tortuous lobar pulmonary arteries with peripheral blunting (Fig. 10-1 and p. 15). The caudal lobar arteries, which are usually the most severely affected, are best evaluated on a dorsoventral (DV) view; the width of these vessels is normally no larger than the ninth rib (at its intersection with the vessels). Enlargement of lobar pulmonary arteries (without concurrent venous distention) is strongly suggestive of HWD or other cause of pulmonary hypertension. An enlarged caudal vena cava also may be seen (see p. 16). Patchy pulmonary interstitial or alveolar infiltrates suggestive of infarction, edema, pneumonia, or fibrosis also are common. These pulmonary opacities may be mainly perivascular. Right-sided CHF caused by HWD is associated with radiographic evidence of severe pulmonary arterial disease and right heart enlargement.

#### **ELECTROCARDIOGRAPHY**

Electrocardiographic (ECG) findings are usually normal, although advanced disease can cause a right axis deviation or an arrhythmia. Dogs with heartworm-induced CHF almost always have ECG criteria for RV enlargement. Tall P waves, suggesting right atrial (RA) enlargement, are sometimes found.

#### **ECHOCARDIOGRAPHY**

Echocardiographic findings in dogs with advanced HWD include RV and RA dilation, RV hypertrophy, paradoxical septal motion, a small left heart, and pulmonary artery dilation. Heartworms located in peripheral pulmonary arteries cannot be seen on echocardiogram. Heartworms within the heart, the main pulmonary artery and its bifurcation, and venae cavae appear as small, bright parallel echos (Fig. 10-2). Suspected caval syndrome can be quickly confirmed by echocardiography. Secondary right-sided CHF may be demonstrated by pleural or pericardial effusion or ascites. Colorflow Doppler can be used in the identification of tricuspid regurgitation even when an audible murmur is absent. Spectral Doppler measurement of maximum tricuspid or pulmonary regurgitant jet velocity allows estimation of pulmonary hypertension severity (see p. 45).

#### CLINICOPATHIC FINDINGS

Eosinophilia, basophilia, and monocytosis are inconsistent hematologic findings. However, fewer than half of dogs with HWD have eosinophilia. Mild regenerative anemia, thought to result from hemolysis, occurs in less than a third of affected dogs. Thrombocytopenia may result from platelet consumption in the pulmonary arterial system, especially after adulticide treatment. DIC also develops in some in dogs with

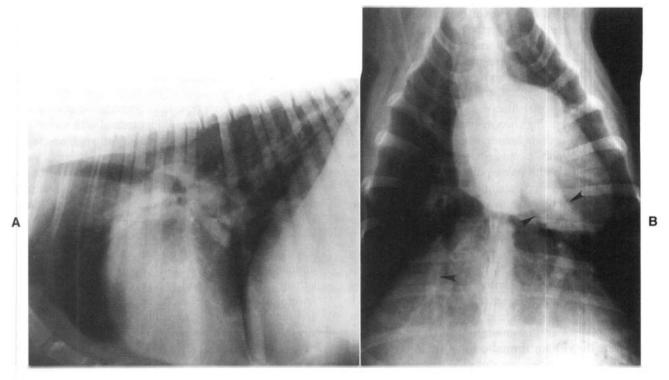

FIG 10-1
Lateral (A) and dorsoventral (B) radiographs from a German Shepherd Dog with advanced heartworm disease. Enlargement of pulmonary arteries is seen, especially on dorsoventral view (arrowheads).

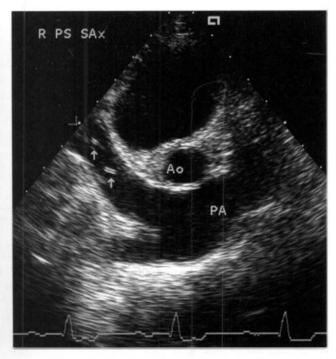

FIG 10-2
Echo image from a dog with severe heartworm disease.
Note the dilated main pulmonary artery (PA) and double-walled echos from heartworms (arrows) in the right PA.
Ao, Aortic root.

advanced disease. The immune response to heartworms produces a polyclonal gammopathy. Mild to moderate elevations in liver enzyme activity and azotemia may occur. Proteinuria is found in 20% to 30% of affected dogs and is more likely with advanced disease. Hypoalbuminemia may develop in severely affected animals.

# Treatment of Dogs with Heartworm Disease PRETREATMENT EVALUATION

As a general rule, adulticide treatment is recommended for dogs infected with heartworms. The withholding of adulticide treatment in some asymptomatic cases remains controversial. Although continuous monthly treatment with prophylactic ivermectin does eventually kill late precardial larvae and young adult worms, this effect occurs over a prolonged time (over 1 to 2 years). Older worms are more resistant to ivermectin and can still cause clinical disease. Furthermore, progression of pulmonary arterial changes, pulmonary disease, and other heartworm-induced effects (e.g., glomerulonephritis) may increase the risk of adulticide treatment should this be undertaken in the future. If adulticide therapy is not given, the dog should at least be treated continuously with ivermectin or possibly with selamectin or moxidectin, which also have some adulticidal effects. Use of heartworm prophylaxis is also important to prevent disease transmission to other animals (by reducing the microfilaremia).

Heartworm-infected dogs should have a thorough history and physical examination. Pretreatment thoracic radiographs provide the best overall assessment of pulmonary arterial and parenchymal disease status. The risk of postadulticide pulmonary thromboembolism is increased in dogs with preexisting clinical and radiographic signs of severe pulmonary vascular disease, especially in those with right-sided CHF or a high worm burden. Other pretreatment tests should include a complete blood count (CBC), serum biochemical profile, and urinalysis. A platelet count is important in animals with severe pulmonary arterial disease. If hypoalbuminemia or proteinuria is detected, a urine protein-creatinine ratio or urine protein loss quantification is advised. Mildly to moderately increased liver enzyme activity may be associated with hepatic congestion, but it does not preclude therapy with melarsomine. Liver enzyme activities usually normalize within 1 to 2 months of heartworm treatment. Some dogs with HWD develop azotemia and/or severe proteinuria. Prerenal azotemia is treated with fluid therapy before adulticide is given. Severe glomerular disease, with loss of antithrombin as well as other proteins, may increase the risk for thromboembolism. Aspirin is not recommended as a routine preadulticide treatment in most dogs because convincing evidence of a beneficial antithrombotic effect is lacking.

The use of prophylactic monthly doses of ivermectin for up to 6 months before the administration of an adulticide in dogs that are clinically stable may be useful. This strategy can reduce heartworm Ag mass by decreasing or eliminating circulating microfilariae and tissue-migrating larvae, stunting immature worm growth, and damaging the adult female reproductive system. Delaying melarsomine for several months also allows any late-stage larvae to mature further, which should increase susceptibility to the adulticidal effect. Microfilaria-positive dogs should be observed in the hospital after the first ivermectin dose in case of adverse reaction. Specific microfilaricide treatment is not necessary before using adulticide.

#### ADULTICIDE THERAPY IN DOGS

Melarsomine dihydrochloride (Immiticide, Merial) is the adulticide of choice. It is effective against both immature and mature heartworms; male worms are more susceptible than females. The worm kill can be controlled by adjusting the dose. An alternative dosing protocol is advised for dogs with more severe disease to promote a more gradual worm kill.

Melarsomine is rapidly absorbed from the intramuscular (IM) injection site. Unchanged drug and a major metabolite are rapidly eliminated in the feces; a minor metabolite is excreted in urine. The drug should be given by deep IM injection into the epaxial lumbar muscles (L3 to L5 region), exactly as recommended by the manufacturer. The lumbar muscle site provides good vascularity and lymphatic drainage with minimal fascial planes. Furthermore, gravity may help prevent the drug from leaking into subcutaneous tissues, where it can cause more irritation. The drug does cause a local reaction at the injection site; this is clinically noticeable

in about a third of treated dogs. Melarsomine is available as a sterile lyophilized powder in 50-mg vials. The rehydrated product is fully stable for 24 hours if kept refrigerated in the dark.

Coughing or gagging and (less often) dyspnea after treatment may be related to the HWD itself, although pulmonary congestion is reported as a toxic effect of overdosing. Most clinical signs noted in dogs treated with melarsomine have been behavioral (e.g., tremors, lethargy, unsteadiness and ataxia, restlessness), respiratory (e.g., panting, shallow breathing, labored respirations, crackles), or injection-site related (e.g., edema, redness, tenderness, vocalization, increased aspartate aminotransferase and creatine kinase activities). Injection site reactions are generally mild to moderate and resolve within 4 (to 12) weeks. Occasionally these reactions are severe. The manufacturer reports that firm nodules may persist indefinitely at the sites. General signs of lethargy, depression, and anorexia occur in about 15% or fewer dogs; other adverse effects, including fever, vomiting, and diarrhea, occur occasionally. Adverse effects are generally mild at recommended doses. Hepatic and renal changes have not proved clinically relevant in animals receiving recommended doses of melarsomine. Overall melarsomine causes less systemic toxicity than its predecessor, thiacetarsamide. Nevertheless, melarsomine has a low margin of safety. Overdose may cause collapse, severe salivation, vomiting, respiratory distress resulting from pulmonary inflammation and edema, stupor, and death. Some clinical reversal of melarsomine toxicity may be achieved with BAL (British Anti-Lewisite or dimercaprol) at a dose of 3 mg/kg, administered intramuscularly. This also decreases adulticide activity.

The HWD severity is used to guide melarsomine therapy (Table 10-2). Standard therapy is used for dogs with mild (class 1) to moderate (class 2) disease. Standard therapy (Box 10-1) involves two doses of 2.5 mg/kg given intramuscularly, 24 hours apart. The manufacturer's administration instructions should be followed carefully. Dogs with severe disease (class 3) or those in class 2 in which a more conservative approach is desired are treated with the alternative dosing regimen. This is designed to partially reduce the worm burden with an initial injection, followed by the standard adulticide regimen 1 month later. The risk of massive pulmonary thromboembolism and death resulting from an initially heavy worm kill is reduced with this protocol. Dogs with caval syndrome (class 4) should not be given adulticide treatment until worms are surgically removed (see p. 177).

Strict rest should be enforced for 4 to 6 weeks after adulticide therapy to reduce the effects of adult worm death and pulmonary thromboembolism (see p. 176). The rest period for working dogs should probably be longer because increased pulmonary blood flow in response to exercise exacerbates pulmonary capillary bed damage and subsequent fibrosis.

Heartworm Ag testing is recommended 6 months after adulticide treatment; results should be negative with successful treatment. Many dogs are heartworm Ag-negative by 4 months after adulticide therapy. Incomplete worm kill is associated with persistent antigenemia. The decision to

**TABLE 10-2** 

#### Classification of Heartworm Disease Severity in Dogs

CLASS	CLINICAL SIGNS	RADIOGRAPHIC SIGNS	LABORATORY ABNORMALITIES
1 (mild)	None; or occasional cough, fatigue on exercise, or mild loss of condition	None	None
2 (moderate)	None; or occasional cough, fatigue on exercise, or mild to moderate loss of condition	Right ventricular enlargement and/or some pulmonary artery enlargement; ±perivascular and mixed alveolar/interstitial opacities	±Mild anemia (PCV to 30%); ±proteinuria (2+ on dipstick)
3 (severe)	General loss of condition or cachexia; fatigue on exercise or mild activity; occasional or persistent cough; ±dyspnea; ±right-sided heart failure	Right ventricular ± atrial enlargement; moderate to severe pulmonary artery enlargement; perivascular or diffuse mixed alveolar/interstitial opacities; ±evidence of thromboembolism	Anemia (PCV < 30%); proteinuria (≥2+ on dipstick)
4 (very severe) Caval syndrome	See p. 177		

PCV, Packed cell volume.

#### BOX 10-1

#### Checklist for Melarsomine (Immiticide) Adulticide Therapy in Dogs

#### Before starting treatment

- 1. Confirm diagnosis.
- 2. Conduct pretreatment evaluation and management.
- 3. Determine class (severity) of disease (see Table 10-2).
- 4. Determine melarsomine (Immiticide) treatment protocol.\* Standard treatment protocol (for class 1 and many class 2 dogs)
- Reconstitute melarsomine as directed by manufacturer. (Use immediately or within 24 hours if refrigerated and protected from light.)
- Draw 2.5 mg/kg of Immiticide into a syringe; attach a new, sterile needle: 23-gauge, 1-inch (2.5-cm) long for dogs <10 kg; or 22-gauge, 1.5-inch (3.75-cm) long for dogs >10 kg.
- Give by deep intramuscular injection into lumbar (epaxial) musculature in the L3 to L5 region; avoid subcutaneous leakage. Record location of first injection.

- 4. Repeat steps 1 to 3 at 24 hours after first dose; use opposite side for second injection.
- Enforce rest for 4 to 6 weeks minimum; symptomatic treatment as needed.

Alternate treatment protocol (for class 3 and some class 2 dogs)

- 1. Provide symptomatic treatment as needed; enforce rest.
- When condition is stable, administer one dose of 2.5 mg/kg as described in the standard treatment protocol.
- Continue enforced rest and symptomatic treatment as needed.
- Between 4 and 6 weeks later, administer two more doses,
   hours apart, according to the standard treatment protocol.

repeat adulticide therapy is guided by the patient's overall health, performance expectations, and age. Complete worm kill is probably not necessary; even if some adult heartworms survive, pulmonary arterial disease improves considerably after adulticide therapy.

Thiacetarsamide is an older adulticide agent that may still be available. It has no advantages and several disadvantages compared with melarsomine. Likewise, the use of other drugs, such as levamisole or stibophen, as adulticides is not recommended. Levamisole does not consistently kill adult heartworms, although it is somewhat effective against male worms and may sterilize adult female worms.

# Postadulticide Pulmonary Thromboembolic Complications

Pulmonary arterial disease worsens from 5 to 30 days after adulticide therapy and is especially severe in previously symptomatic dogs. It occurs because dead and dying worms lead to thrombosis and pulmonary artery obstruction, with exacerbation of platelet adhesion, myointimal proliferation,

<sup>\*</sup>See p. 174 for more information.

villous hypertrophy, granulomatous arteritis, perivascular edema, and hemorrhage. Pulmonary blood flow obstruction and increased vascular resistance further strain the right ventricle and increase oxygen demand. Poor cardiac output, hypotension, and myocardial ischemia may result. Severe ventilation-perfusion mismatch may result from pulmonary hypoperfusion, hypoxic vasoconstriction and bronchoconstriction, pulmonary inflammation, and fluid accumulation. Pulmonary thromboembolization is most likely to occur 7 to 17 days after adulticide therapy. As expected, the caudal and accessory lung lobes are most commonly and severely affected.

Depression, fever, tachycardia, tachypnea or dyspnea, and cough are common clinical signs. Hemoptysis, right-sided CHF, collapse, or death may also occur. Interstitial and alveolar pulmonary inflammation and fluid accumulation cause pulmonary crackles on auscultation. Focal lung consolidation may cause areas of muffled lung sounds. Thoracic radiographs show patchy alveolar infiltrates with air bronchograms, especially near the caudal lobar arteries. Thrombocytopenia or neutrophilia with a left shift may be seen on CBC.

Treatment of pulmonary thromboembolism includes strict rest (i.e., cage confinement) and glucocorticoid therapy to reduce pulmonary inflammation (prednisone, 1 to 2 mg/ kg/day by mouth initially, then tapering). Supplemental oxygen therapy is recommended to reduce hypoxiamediated pulmonary vasoconstriction. A bronchodilator (e.g., oral aminophylline, 10 mg/kg IM or IV q8h; or oral theophylline, 9 mg/kg q6-8h), judicious fluid therapy (if there is evidence of cardiovascular shock), and cough suppressants may be useful. Antibiotics have been given empirically, but they are of questionable benefit unless there is evidence of concurrent bacterial infection. Hydralazine has reduced pulmonary vascular resistance experimentally, and some dogs seem to respond clinically to diltiazem. Systemic hypotension and tachycardia must be avoided when using a vasodilator. Aspirin is not recommended because there is no convincing evidence that it prevents thrombosis or reduces pulmonary arteritis. Heparin (200 to 400 U/kg sodium heparin administered subcutaneously q8h, or 50 to 100 U/kg calcium heparin administered subcutaneously q8-12h) may be considered for severe cases of thromboembolism. However, excessive bleeding is a possible serious adverse effect. Low-molecular-weight heparin might provide a safer alternative to unfractionated heparin, but definitive recommendations are not yet available.

Endothelial changes in survivors regress within 4 to 6 weeks. Pulmonary hypertension and arterial disease, along with radiographic changes, diminish over the next several months. Eventually, pulmonary arterial pressure and the contour of the proximal pulmonary arteries normalize, although some fibrosis may remain.

#### Treatment of Dogs with Complicated HWD

#### **PULMONARY COMPLICATIONS**

Immune-mediated pneumonitis occurs in some dogs. Allergic or eosinophilic pneumonitis develops in a minority of

dogs with occult HWD. Clinical manifestations of heartworm pneumonitis include a progressively worsening cough, crackles heard on auscultation, tachypnea or dyspnea, and sometimes cyanosis, weight loss, and anorexia. Eosinophilia, basophilia, and hyperglobulinemia are inconsistent findings. Heartworm Ag tests are usually positive. Diffuse interstitial and alveolar infiltrates, especially in the caudal lobes, are common on radiographs; these can be similar to those in dogs with pulmonary edema or blastomycosis. There is often no clinically relevant cardiomegaly or pulmonary lobar artery enlargement. Tracheal wash cytology usually reveals a sterile eosinophilic exudate with variable numbers of well-preserved neutrophils and macrophages. Therapy with a glucocorticoid (prednisone, 1-2 mg/kg/day by mouth initially) usually results in rapid and marked improvement. Prednisone may be continued as needed, in gradually tapered doses (to 0.5 mg/kg every other day) and does not appear to adversely affect the adulticide efficacy of melarsomine.

Pulmonary eosinophilic granulomatosis is an uncommon syndrome that has been associated with HWD, although some affected dogs have negative heartworm tests. Its pathogenesis is thought to involve a hypersensitivity reaction to heartworm Ag or immune complexes, or both. Pulmonary granulomas comprise a mixed mononuclear and neutrophilic cell population, with many eosinophils and macrophages. A proliferation of bronchial smooth muscle within granulomas and an abundance of alveolar cells in the surrounding area are common findings. Lymphocytic and eosinophilic perivascular infiltrates may also occur. Eosinophilic granulomas involving the lymph nodes, trachea, tonsils, spleen, GI tract, and the liver or kidneys may occur concurrently. The clinical signs of pulmonary eosinophilic granulomatosis are similar to those of eosinophilic pneumonitis. Clinicopathologic findings variably include leukocytosis, neutrophilia, eosinophilia, basophilia, monocytosis, and hyperglobulinemia. In some cases an exudative, primarily eosinophilic pleural effusion develops. Radiographic findings include multiple pulmonary nodules of varying size and location with mixed alveolar and interstitial pulmonary infiltrates; hilar and mediastinal lymphadenopathy may also be present. Eosinophilic granulomatosis is treated initially with prednisone (1 to 2 mg/kg q12h); however, additional cytotoxic therapy may be needed as well. Not all dogs respond completely, and relapses are common, especially when therapy is reduced or discontinued. The response to immunosuppressive drugs after relapse may be poor. Therapy for adult heartworms is given when pulmonary disease improves.

Severe pulmonary arterial disease is more common in dogs with long-standing heartworm infection, in those with many adult worms, and in active dogs. Severe cough, exercise intolerance, tachypnea or dyspnea, episodic weakness, syncope, weight loss, and ascites are common clinical signs; death sometimes occurs. Typical radiographic findings include markedly enlarged, tortuous, and blunted pulmonary arteries. Pulmonary parenchymal infiltrates leading to hypoxemia are seen in some cases; these are treated with prednisone as described in the preceding paragraph. Throm-

bocytopenia and hemolysis may occur in dogs with severe pulmonary arterial disease and thromboembolism. Monitoring of platelet count and packed cell volume is recommended. DIC develops in some dogs. Conservative therapy with oxygen, prednisone, and a bronchodilator (e.g., theophylline), as for postadulticide pulmonary thromboembolism, should help improve oxygenation and reduce pulmonary artery pressures. Alternate-day, low-dose prednisone (e.g., 0.5 mg/kg orally) is thought to have beneficial antiinflammatory effects, although long-term use of high corticosteroid doses may reduce pulmonary blood flow, increase risk of thromboembolism, and inhibit vascular disease resolution.

After the animal's condition is stabilized, the alternative melarsomine protocol may be used. Use of aspirin is discouraged, especially with hemoptysis. Prophylactic antibiotics are sometimes recommended because of the potential for secondary bacterial infections in devitalized pulmonary tissue.

## RIGHT-SIDED CONGESTIVE HEART FAILURE

Severe pulmonary arterial disease and pulmonary hypertension can cause CHF. Jugular venous distention or pulsation, ascites, syncope, exercise intolerance, and arrhythmias are typical signs. Pleural or pericardial effusion as well as other signs secondary to pulmonary arterial and parenchymal disease may also occur. Treatment is the same as for dogs with severe pulmonary arterial disease, with the addition of furosemide (e.g., 1-2 mg/kg/day), an angiotensin-converting enzyme inhibitor (ACEI; e.g., enalapril 0.5 mg/kg q12-24 h by mouth), and a sodium-restricted diet. Use of digoxin in these cases is controversial; pimobendan has not been evaluated in this setting but could be useful.

#### CAVAL SYNDROME

The (vena) caval syndrome occurs in heavily infected animals when venous inflow to the heart is obstructed by a mass of worms, leading to low-output cardiovascular shock. Other terms for this condition include postcaval syndrome, acute hepatic syndrome, liver failure syndrome, dirofilarial hemoglobinuria, and vena cava embolism. As the heartworm burden increases, adult worms migrate to the right atrium and caudal vena cava from their preferred locations in the pulmonary artery and right ventricle. Factors other than worm burden alone are probably also involved in the development of the caval syndrome, including degree of pulmonary hypertension. Caval syndrome occurs more often in geographic areas where HWD is enzootic; up to 20% of dogs with HWD are estimated to be affected in some areas.

Most dogs that develop caval syndrome have no history of heartworm-related signs. Acute collapse is common, often accompanied by anorexia, weakness, tachypnea or dyspnea, pallor, hemoglobinuria, and bilirubinuria. A tricuspid insufficiency murmur, jugular distention and pulsations, weak pulses, a loud and possibly split S<sub>2</sub>, and a cardiac gallop rhythm are often found. Sometimes coughing or hemoptysis and ascites occur. Tricuspid insufficiency and partial occlusion of RV inflow caused by a mass of worms, in conjunction

with pulmonary hypertension, lead to the development of right-sided congestive signs and poor cardiac output.

Clinicopathologic findings may include microfilaremia, Coombs-negative fragmentation hemolytic anemia (from red blood cell trauma), azotemia, abnormal liver function, and increased liver enzyme activities; DIC is common. Intravascular hemolysis results in hemoglobinemia and hemoglobinuria. Thoracic radiographs indicate right heart and pulmonary artery enlargement. The ECG usually suggests RV enlargement. Ventricular or supraventricular premature complexes are common. Echocardiography reveals a mass of worms entangled at the tricuspid valve and in the right atrium and venae cavae (Fig. 10-3). RV dilation and hypertrophy, paradoxical septal motion, and a small left ventricle are also typical.

Most dogs die within 24 and 72 hours as a result of cardiogenic shock complicated by metabolic acidosis, DIC, and anemia unless they are aggressively treated. Worms must be surgically removed from the vena cava and right atrium as soon as possible. The dog is lightly sedated, if necessary, and local anesthesia is used. A right jugular venotomy with the dog restrained in left lateral recumbency is the usual approach. Long alligator forceps, an endoscopic basket retrieval instrument, or horsehair brush device are used to grasp and withdraw the heartworms through the jugular vein incision. The instrument is gently passed down the vein into the right atrium; repositioning of the animal's head and neck may be necessary to pass the instrument beyond the thoracic inlet. The goal is to retrieve as many worms as possible; generally, five to six unsuccessful attempts in sequence is the end point. Resistance to instrument withdrawal from the vein may occur if too many worms are grasped at once or a cardiovascular structure is grabbed by forceps. Survival rates of 50% to 80% have been reported for dogs undergoing this procedure. Another technique that has been used in very small dogs is right auricular cannulation performed via a thoracotomy to remove worms. (See Suggested Readings for more information on this technique.)

Cautious intravenous (IV) fluid administration with other supportive care is provided during and after surgical worm removal. Central venous pressure monitoring helps the clinician assess the effectiveness of worm removal and fluid therapy. Treatment with a positive inotrope or sodium bicarbonate is usually not necessary, but a broad spectrum antibiotic is recommended. Monitoring for anemia, thrombocytopenia, DIC, and organ dysfunction is important; treatment is given as indicated. Severe pulmonary thromboembolism and renal or hepatic failure are associated with poor outcome. Dogs that survive acute caval syndrome can be treated with adulticide within a few weeks after stabilization to eliminate remaining worms. The use of a flexible alligator forceps with fluoroscopic or transesophageal echo guidance has been advocated as a way to reduce the worm burden in the main pulmonary artery and lobar branches before adulticide therapy. This can reduce the risk for postadulticide thromboembolism in heavily infected dogs, although technical issues and the need for heavy sedation or anesthesia may be limitations.

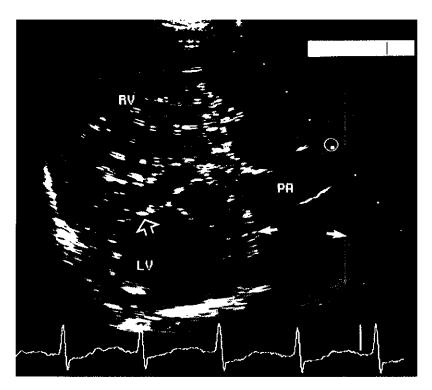

FIG 10-3

Echocardiogram from a 9-year-old male mixed-breed dog with caval syndrome. The transducer is in the right parasternal short-axis position at a level just below the aorta. The image shows the enlarged and hypertrophied right ventricle and its outflow tract. Many small, bright parallel echoes are apparent in the body of the right ventricle (RV) in this diastolic frame and are caused by a clump of heartworms entangled in the tricuspid valve apparatus. Note also the widened main pulmonary artery segment typical of pulmonary hypertension (small arrows). The interventricular septum is flattened and pushed toward the left ventricle (LV) by high right ventricular pressure (open arrow). The LV itself is small because the heartworms obstruct blood flow through the right heart. PA, Main pulmonary artery.

#### MICROFILARICIDE THERAPY

Specific microfilaricidal therapy for dogs with circulating microfilariae may be given 3 to 4 weeks after adulticide therapy, but the gradual microfilaricidal effect of monthly preventive drugs has largely replaced the need for this treatment. Oral ivermectin (at 50 µg/kg) and milbemycin oxime (at standard preventive dose) can rapidly reduce microfilariae. Ivermectin at this dose is safe for Collies. The rapid death of many microfilariae can cause systemic effects within 3 to 8 (and occasionally 12) hours of the first dose; these include lethargy, inappetence, excessive salivation, retching, defecation, pallor, and tachycardia. Such adverse effects are usually mild, but dogs with a high number of circulating microfilariae may experience circulatory collapse. This condition generally responds to glucocorticoid therapy (e.g., prednisolone sodium succinate, 10 mg/kg, or dexamethasone, 1 mg/kg, administered intravenously) and IV fluid administration (e.g., 80 ml/kg over 2 hours) if these are instituted promptly. All cases should be closely observed for 8 to 12 hours after initial microfilaria treatment with either macrolide. An additional benefit is protection against new infection. Moxidectin and selamectin are also known to be microfilaricidal, but clinical experience for this purpose is lacking. Other drugs used as microfilaricides in the past (e.g., levamisole and fenthion) are not recommended because of lower efficacy and frequent adverse effects.

#### **HEARTWORM PREVENTION**

Heartworm prophylaxis is indicated for all dogs living in endemic areas. The time of year that infection can occur is limited in many geographic areas, because sustained warm, moist conditions are needed for transmission of the disease. Transmission can occur only during a few months in the most northern parts of the United States and Canada; year-round transmission is likely only in the far south of the continental United States. Although monthly preventive therapy may be necessary only during June through November in most of the United States, continuous chemoprophylaxis throughout the year may be more practical in locations where transmission is likely during more than half the year.

Several drugs are currently available for preventing heartworm disease: the avermectins (ivermectin, selamectin) and the milbemycins (milbemycin oxime, moxidectin). Diethycarbamazine (DEC) is another choice, but it must be given daily. The avermectins and milbemycins induce neuromuscular paralysis and death in nematode (and arthropod) parasites by interacting with membrane chloride channels. They are effective against third- and fourth-stage larvae and sometimes young adult worms as well as microfilariae; however, milbemycin is least effective against adult *D. immitis*. Retroactive efficacy (reachback) with these agents lasts at least 1 and possible more than 2 months after a single dose. These agents are quite safe in mammals when used as directed, even in sensitive Collies. Cases of clinical toxicity have usually been related to dosage miscalculation using a concentrated livestock preparation.

The avermectins and milbemycins are packaged in monthly dose units according to body weight ranges. Dosing should begin within 1 month of the start of the heartworm transmission season and continue to within 1 month after the transmission season ends. Year-round administration may be preferable depending on location. Drugs available for monthly oral administration include ivermectin (6-12 µg/ kg; Heartgard, Merial), milbemycin oxime (0.5-1.0 mg/kg; Interceptor, Novartis Animal Health), and moxidectin (3 µg/ kg; ProHeart, Fort Dodge Animal Health). Selamectin (Revolution, Pfizer Animal Health) is applied to the skin between the shoulder blades at a monthly dose range of 6-12 mg/kg; efficacy is not affected if bathing or swimming is delayed at least 2 hours after application. Some of these agents are effective against other parasites at the doses used for heartworm prevention (e.g., hookworms with milbemycin; fleas, earmites, and ticks with selamectin). These drugs are also sometimes marketed in combination with other antiparasitic agents for broader protection against endoparasites and ectoparastites.

DEC (at 3 mg/kg, or 6.6 mg/kg of the 50% citrate, by mouth once daily) has been used for decades to prevent HWD. The drug is thought to affect the heartworm's L<sub>3</sub> to L<sub>4</sub> molting stage at 9 to 12 days after infection. The drug may be discontinued 2 months after a killing frost in regions with cold winters and reinstituted 1 month before mosquito season in the spring. Before beginning (or restarting) DEC treatment, dogs must be negative for microfilariae (see p. 170). Puppies 6 months of age and older also should be tested for microfilariae. Annual microfilaria tests are strongly recommended, even in areas where the drug is given yearround. To be effective, DEC must be given daily. If a lapse in DEC administration of <6 weeks has occurred, one dose of a monthly preventive drug should restore protection. For longer lapses, monthly chemoprophylaxis should be extended for a year. Microfilaria-positive dogs should not be given DEC. Adverse reactions of variable severity may occur, especially in dogs with higher numbers of microfilariae. These may include lethargy progressing to vomiting, diarrhea, and bradycardia; some patients develop hypovolemic shock, with tachypnea, tachycardia, recumbency, hypersalivation, and eventually death. IV dexamethasone (at least 2 mg/kg), fluids, and other supportive measures have been used to treat the hypovolemia and shock; atropine is used for severe bradycardia. Dogs with this microfilaria-induced reaction that do not show clinical improvement within 3 to 5 hours are likely to die. Dogs without circulating microfilariae may be given DEC. Those on DEC prophylaxis that are subsequently discovered to have circulating microfilariae may be continued on the drug without interruption during adulticide and microfilaricide therapy to prevent reinfection.

Preventive therapy can begin at 6 to 8 weeks of age. Dogs old enough to have been previously infected should be tested for circulating Ag and (if DEC is to be used) microfilariae before chemoprophylaxis is initially begun. Retesting for heartworm Ag every 2 to 3 years is probably adequate when monthly preventive agents are used. When DEC is chosen as a preventive, yearly microfilaria testing is important before DEC is reinstituted.

#### **HEARTWORM DISEASE IN CATS**

#### **Pathophysiology**

In cats the pathophysiologic changes associated with HWD occur in two stages. Approximately 3 to 6 months after infection, immature worms arrive, and may die, in the pulmonary arteries. This stimulates pulmonary intravascular macrophage activation. These specialized phagocytic cells are located in the pulmonary capillary beds of cats but not dogs. Activation of these macrophages leads to acute inflammation in the pulmonary arteries and lung tissue. Adventitial and perivascular inflammatory cell infiltrates of eosinophils and neutrophils are seen as well. Cats also have more extensive alveolar type 2 (surfactant-producing) cell hyperplasia than dogs, which can interfere with alveolar O2 exchange. The parenchymal lesions are thought to play an important role in the development of acute respiratory distress in cats 3 to 9 months after infection. The acronym HARD (heartworm-associated respiratory disease) has been proposed for the lesions and subsequent clinical signs that may result from the death of L<sub>5</sub> larvae in the lungs of these cats. Although some cats recover, this phase is fatal in others. Sudden death can occur.

In cats that survive, the acute inflammation subsides. Vascular injury leads to myointimal proliferations and muscular hypertrophy in affected pulmonary arteries. These lesions tend to be focal. This may be why clinically relevant pulmonary hypertension, secondary RV hypertrophy, and right-sided CHF are uncommon in cats. Dead and degenerating worms cause recrudescence of pulmonary inflammation and thromboembolism. Disease is most severe in the caudal lung lobes. Caudal lobar arterial obstruction can be caused by villous proliferation, thrombi, or dead heartworms. Adult worms are more likely to obstruct the pulmonary arteries of cats (compared with dogs) by virtue of their relative size. The bronchopulmonary circulation in cats is thought to prevent pulmonary infarction.

Vomiting is common in cats with HWD. The mechanism for this may involve central stimulation (of the chemoreceptor trigger zone) by inflammatory mediators. Antiinflammatory doses of a glucocorticoid often control this sign. Infected cats generally have fewer adult worms than do infected dogs. Heartworms mature more slowly, fewer numbers of infective larvae mature to adults, and the adult life span is shorter in cats. However, live worms can persist for 2 to 3 years. Heartworm-infected cats generally have fewer than eight adult worms in the RV and pulmonary arteries, and most cats have only one or two worms. Nevertheless, even one adult worm can cause death. Unisex infection is common. Most cats have no or only a brief period of microfilaremia. Aberrant worm migration is also more common in cats than dogs and complicates necropsy confirmation of infection. Aberrant sites have included the brain, subcutaneous nodules, body cavities, and occasionally a systemic artery.

#### **Clinical Features**

Most reported cases have occurred in cats 3 to 6 years of age, although cats of any age are susceptible. Domestic Shorthair cats seem to be overrepresented. Male cats are overrepresented in some but not all studies. Cats living strictly indoors are not protected from infection. Infection is self-limiting in some cats. Some researchers have noted an increase in HWD diagnosis during fall and winter, presumably after infection in the spring, but others have found fewer cases in the latter part of the year.

Clinical signs are variable and may be transient or nonspecific. Respiratory signs occur in more than half of symptomatic cats, especially dyspnea and/or paroxysmal cough, which can mimic feline asthma. Other client complaints include lethargy, anorexia, vomiting, syncope, other neurological signs, and sudden death. Vomiting, usually unrelated to eating, is common and may be the only sign in some infected cats. Severe clinical signs are usually associated with the arrival of L<sub>5</sub> worms in the pulmonary arteries (and HARD surrounding the death of some L<sub>5</sub>) and also with thromboembolism after the death of one or more adult worms. The sudden onset of neurologic signs, with or without anorexia and lethargy, is common during aberrant worm migration. Such signs include seizures, dementia, apparent blindness, ataxia, circling, mydriasis, and hypersalivation. Only rarely do cardiopulmonary and neurologic signs co-exist. Although heartworms can cause significant pulmonary disease, some cats have no clinical signs.

Auscultation may reveal pulmonary crackles, muffled lung sounds (either from pulmonary consolidation or pleural effusion), tachycardia, and sometimes a cardiac gallop sound or murmur. Pleural effusion caused by right-sided CHF, as well as syncope, is less common in cats than in dogs with HWD. However, chylothorax and ascites are occasionally associated with HWD in cats, and pneumothorax occurs rarely. There are sporadic reports of caval syndrome in cats.

Peracute respiratory distress, ataxia, collapse, seizures, hemoptysis, or sudden death may occur.

#### **Diagnosis**

Definitive diagnosis is more difficult in cats than dogs. A combination of serologic testing (see p. 170), thoracic radio-

graphs, and echocardiography is used. Microfilaria testing is only occasionally helpful.

#### TESTS FOR HEATWORM DISEASE IN CATS Serologic Tests

Feline heartworm Ab tests are often used for screening; however, although they are fairly sensitive, they are not specific for adult heartworms. The ELISA-based Ag tests are highly specific in detecting adult heartworm infection, but their sensitivity depends on the gender, age, and number of worms. Serologic test results may be negative early in the infection, although the cat may have clinical signs. Ag test results are negative during the first 5 months after infection and may be variably positive at 6 to 7 months; infections with mature female worms should be detected after 7 months. False-negative heartworm Ag test results are more likely in cats because worm burden is typically low; also, a longer time is required for cats to become Ag positive. Acute death and severe clinical signs may occur in Ag-negative cats. Furthermore, postmortem diagnosis may be difficult if the worms are located in distal pulmonary arteries or aberrant sites. Occasionally, a positive Ag test result occurs but no worms are found on postmortem examination. Spontaneous worm death, worms overlooked during pulmonary evaluation, and ectopic infection are likely reasons for this finding.

#### **RADIOGRAPHY**

Radiographic findings that suggest HWD include pulmonary artery enlargement with or without visible tortuosity and pruning, RV or generalized cardiac enlargement, and diffuse or focal pulmonary bronchointerstitial infiltrates (Fig. 10-4). Pulmonary hyperinflation is sometimes evident. The pulmonary artery and right heart changes are typically more subtle in cats than dogs. Radiographic findings may not correlate with clinical signs or results of serologic tests. Pulmonary artery distention may be greatest within the first 7 months of infection; some regression may occur subsequently, especially in cranial arteries. The DV view is best for evaluating caudal lobar arteries; these are more frequently abnormal on radiographs. The right caudal lobar artery may be more prominent; however, a left caudal pulmonary artery ≥1.6 multiplied by the width of the ninth rib at the ninth intercostal space was reported as the most discriminating radiographic finding for separating heartworm-infected from non-infected cats (Schafer et al., 1995). The main pulmonary artery segment is not usually visible on DV or ventrodorsal views in cats because its location is more medial than it is in dogs. Marked right heart enlargement is more likely when signs of right-sided CHF (e.g., pleural effusion) exist. Thoracocentesis may be necessary to evaluate the heart, pulmonary vasculature, and lung parenchyma when there is pleural effusion. Ascites occurs in some cats with HWD, but it is rare in cats with heart failure resulting from cardiomyopathy.

Both heartworm-associated pneumonitis as well as pulmonary thromboembolism produce pulmonary infiltrates;

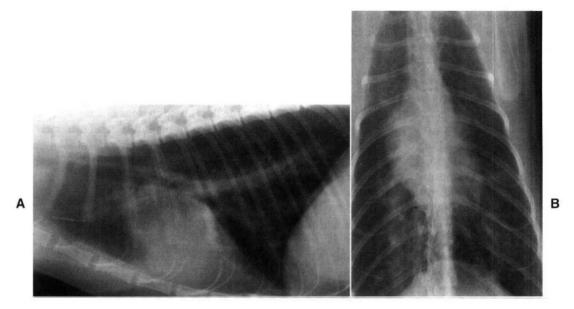

FIG 10-4
Lateral (A) and dorsoventral (B) radiographs from a cat with heartworm disease. There are interstitial infiltrates throughout the lung fields and enlarged pulmonary arteries seen on both views.

focal perivascular and interstitial opacities are more common than diffuse infiltrates. Radiographs are normal in a small minority of heartworm-infected cats.

Pulmonary arteriography may confirm a suspected diagnosis of HWD in a cat with a false-negative Ag test result and normal echocardiogram. The study may be performed using a large-bore jugular catheter. Morphologic changes in the pulmonary arteries are outlined, and worms appear as linear filling defects.

#### **ECHOCARDIOGRAPHY**

Echocardiographic findings may be normal unless worms are located in the heart, main pulmonary artery segment, or proximal left and right pulmonary arteries. However, heartworms may be visualized in about one half to three fourths of infected cats. Higher numbers of worms increase the likelihood of identification with echocardiography. Because worms are seen more often in the pulmonary arteries than in right heart chambers, an index of suspicion and careful interrogation of these structures are important.

#### **ELECTROCARDIOGRAPHY**

ECG findings are often normal, but most cats with heart-worm-induced CHF have changes suggesting RV enlargement. Arrhythmias appear to be uncommon. Advanced pulmonary arterial disease and CHF are more likely to cause ventricular tachyarrhythmias.

#### OTHER TESTS

Between one and two thirds of infected cats have peripheral eosinophilia, usually from 4 to 7 months after infection. Many times the eosinophil count is normal; basophilia is uncommon. About one third of the cases have mild nonre-

generative anemia. Advanced pulmonary arterial disease and thromboembolism may be accompanied by neutrophilia (sometimes with a left-shift), monocytosis, thrombocytopenia, and DIC. Hyperglobulinemia, the most common biochemical abnormality, occurs inconsistently. The prevalence of glomerulopathies in cats with HWD is unknown, but it does not appear to be high.

Tracheal wash or bronchoalveolar lavage specimens may show an eosinophilic exudate that suggests allergic or parasitic disease, similar to that found with feline asthma or pulmonary parasites. This finding usually occurs between 4 and 8 months after infection. Later in the disease, tracheal wash findings may be unremarkable or indicate nonspecific chronic inflammation. Pleural effusion resulting from heartworm-induced CHF is generally a modified transudate, although chylothorax occasionally develops.

At around 6.5 to 7 months after infection, a transient (1 to 2 months in duration), low-grade microfilaremia occurs in about half of infected cats. Therefore microfilaria concentration tests are usually negative. Nevertheless, a concentration test may still prove valuable in some individual cats. Between 3 and 5 ml, rather than 1 ml, of blood should be used to increase the probability of detecting microfilariae.

#### Treatment of Cats with Heartworm Disease

# MEDICAL THERAPY AND COMPLICATIONS

Adulticide therapy is not recommended in most cases because the likelihood of severe complications in this species is high. Also, spontaneous cure is possible in cats because of the shorter heartworm life span, and cats are not significant reservoirs for HWD transmission to other animals. On the basis of a retrospective study (Atkins et al., 2000), cats treated with thiacetarsamide had no survival advantage over those that were not treated with adulticide.

The recommended, and more conservative, approach for infected cats is to use prednisone as needed for respiratory signs and radiographically evident pulmonary interstitial infiltrates. A monthly heartworm preventive drug is also advised but not a heartworm adulticide. Serologic tests (for heartworm Ab and Ag) are obtained every 6 to 12 months to monitor infection status. Ag-positive cats usually become negative within 4 to 5 months of worm death. It is unclear how long Ab tests remain positive. Serial thoracic radiographs and echocardiograms also can be useful for monitoring cats that have had abnormal findings. Interstitial pulmonary infiltrates usually respond to prednisone (e.g., 2 mg/kg/day by mouth, reduced gradually over 2 weeks to 0.5 mg/kg god, then discontinued after 2 more weeks). Prednisone therapy may be repeated periodically if respiratory signs recur.

The possibility of severe respiratory distress and death is always present, especially after spontaneous or adulticideinduced worm death. Pulmonary thromboembolism is more likely to produce a fatal outcome in cats than dogs. Clinical findings with pulmonary thromboembolism include fever, cough, dyspnea, hemoptysis, pallor, pulmonary crackles, tachycardia, and hypotension. Radiographic signs include poorly defined, rounded or wedge-shaped interstitial opacities that obscure associated pulmonary vessels. Alveolar infiltrates are seen in some cases. Cats with acute disease are given supportive care, which may include an IV glucocorticoid (e.g., 100 to 250 mg prednisone sodium succinate), fluid therapy, a bronchodilator, and supplemen-tal oxygen. Diuretics are not indicated. Aspirin is currently not recommended for cats with HWD. Aspirin and other nonsteroidal antiinflammatory drugs have not been shown to produce benefit and may exacerbate pulmonary disease.

Right-sided CHF develops in some cats with severe pulmonary arterial disease. Cough and other signs of pulmonary interstitial disease or a thromboembolic event occur inconsistently. Dyspnea (caused by pleural effusion) and jugular venous distention or pulsation are common. Radiographic and ECG findings usually suggest RV enlargement. Therapy is directed at controlling the signs of heart failure. This includes thoracocentesis as needed, cage rest, and cautious furosemide therapy (e.g., 1 mg/kg q12-24h). An ACEI may be helpful. Digoxin is not usually recommended. Pimobendan might be considered, but clinical experience is lacking. The cat's clinical progress and clinicopathologic abnormalities are used to guide supportive therapy.

Caval syndrome occurs rarely in cats. Successful removal of adult worms through a jugular venotomy is possible.

Adulticide therapy may be considered for cats that continue to manifest clinical signs despite prednisone treatment. Potentially fatal thromboembolism can occur, even with only one worm present. About a third of adulticide-treated cats are expected to have thromboembolic complica-

tions. The risk is expected to be higher for heavily infected cats. An adulticide should never be given only on the basis of a positive Ag, Ab, or microfilaria test result. There is little clinical experience with melarsomine (Immiticide) in cats. Doses of >3.5 mg/kg appear to be toxic in this species. IV thiacetarsamide (Caparsolate) has been used successfully at the same doses used in dogs (2.2 mg/kg q12h for 2 days) in combination with prednisone and extremely close monitoring for 2 weeks. Acute respiratory failure and death may occur as a result of dying worms or toxic effects of the arsenical drug. Profound depression and GI side effects also are common after each dose. Pretreatment with an antihistamine and soluble glucocorticoid before thiacetarsamide administration is of unknown efficacy. The effectiveness of chronic ivermectin at the recommended prophylactic dose against juvenile worms in cats is not known. Results of adult worm Ag tests should be negative within 3 to 4 months of successful adulticide therapy; the time required for Ab titers to become negative is likely much longer.

#### SURGICAL THERAPY

Several approaches are described for removing adult heartworms from cats, although they are technically challenging. A right jugular venotomy may be used to reach worms in the right atrium and vena cava with small alligator forceps, endoscopic grasping or basket retrieval forceps, or another device. Worm removal via thoracotomy and right atriotomy has also been done successfully. A left thoracotomy and pulmonary arteriotomy may permit worm extraction from within the pulmonary artery. A potentially fatal anaphylactic reaction associated with worm breakage could occur during such procedures. Presurgical treatment with a glucocorticoid and antihistamine has been suggested. It is not known whether pretreatment with heparin for several days can reduce thromboembolism associated with surgical worm removal.

#### MICROFILARICIDE THERAPY

Microfilaricide therapy is rarely necessary because microfilaremia is brief. However, ivermectin and milbemycin should be effective in this setting.

#### **Heartworm Prevention in Cats**

Heartworm prophylaxis is recommended for cats in endemic areas. Selamectin (Revolution), ivermectin (Heartgard for cats), and milbemycin oxime (Interceptor Flavor Tabs for Cats) are effective preventive drugs in cats. Selamectin is used at the same dose as for dogs (6-12 mg/kg, topically). Selamectin also is useful for controlling fleas and earmites as well as hookworm and roundworm infections in cats. Ivermectin is administered orally at 24 µg/kg monthly (four times the dose used in dogs). The minimum recommended dose for milbemycin is 2 mg/kg (about twice the dose used in dogs). All these agents are safe in kittens 6 weeks or older. A heartworm Ag test is recommended before beginning prophylaxis if infection could have occurred 8 months or more in the past. These agents may be used in seropositive cats.

The efficacy of moxidectin or DEC for heartworm prevention in cats is not known.

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
Blood Pressure Measurement
Antihypertensive Drugs
Hypertensive Emergency

#### **GENERAL CONSIDERATIONS**

Over time, marked elevation of arterial blood pressure (BP) can cause serious clinical consequences. Various factors influence values obtained for systolic, diastolic, and mean arterial BP in healthy animals. Breed-related variation and variations related to age, gender, reproductive status, and other factors can occur. An average normal BP across breeds of dog is about 133/75 mm Hg (systolic/diastolic), and an average normal BP in cats is about 124/84 mm Hg, using oscillometric methods. However, breed-related variations should always be taken into account; for example, because Greyhounds have higher systolic BP and Irish Wolfhounds lower systolic BP than other breeds, the recommendations of the Veterinary Blood Pressure Society should be interpreted with caution. Variation in measured BP may be related to technique (direct and various noninvasive methods) as well as to patient anxiety. Systolic BP can exceed 180 mm Hg in some stressed normal animals. The demarcation between acceptable and "abnormally high" arterial BP is not clear-cut. Furthermore, although some dogs and cats clearly have clinical disease caused by hypertension, many with "abnormally high" BP have no evidence of related pathology, although a predisposing disease condition may exist. Repeated BP measurements over time along with careful clinical evaluation are indicated when considering a diagnosis of hypertension.

Guidelines from the Veterinary Blood Pressure Society suggest that repeatable (on at least three occasions) pressure measurements of 150 to 160 mm Hg systolic and 95 to 100 mm Hg diastolic constitute mild hypertension; an additional 20 mm Hg is allowed for specific breed differences

(e.g., for some sight hounds). Moderate hypertension is associated with BPs between 160 and 180 mm Hg systolic and 100 and 120 mm Hg diastolic (plus ~30 mm Hg for specific breed differences). Arterial pressures >180/120 mm Hg (plus ~50 mm Hg for specific breeds) indicate severe hypertension.

Mild hypertension generally does not require antihypertensive therapy, although any underlying disease should be addressed. Some animals with moderate hypertension also may not need specific antihypertensive therapy. However, severe hypertension should be treated to prevent or reduce end-organ damage. Some animals require urgent antihypertensive therapy (see p. 190). If antihypertensive therapy is used, close monitoring for efficacy, adverse effects, and deterioration of underlying conditions is warranted.

#### Etiology

Hypertension is usually associated with other diseases (Box 11-1) rather than being a primary condition (idiopathic or essential hypertension) in dogs and cats. There is a high prevalence of at least mild hypertension in cats with renal disease or hyperthyroidism. Renal disease, especially involving glomerular function, and hyperadrenocorticism are commonly associated with hypertension in dogs; diabetes mellitus, hypothyroidism, and liver disease may also be associated with higher BP. Because of the increased risk for hypertension in patients with such conditions, BP should be measured when diagnosing the disease as well as periodically thereafter. Similarly, hypertension discovered during a routine exam may be an early marker of such underlying disease. Certain drugs, such as glucocorticoids, mineralocorticoids, nonsteroidal antiinflammatory agents, phenylpropanolamine, sodium chloride, and even topical ocular phenylephrine, can increase BP. Obesity is known to increase BP mildly in dogs. Inherited idiopathic (essential) hypertension has been documented in dogs and cats, but it is uncommon. Idiopathic hypertension is considered a diagnosis of exclusion.

#### **Pathophysiology**

BP depends on the relationship between cardiac output and peripheral vascular resistance. BP is increased by conditions

BOX 11-1

#### Diseases Associated with Hypertension

#### Documented or Suspected Causes in Dogs and Cats

Renal disease (tubular, glomerular, vascular)

Hyperadrenocorticism

Hyperthyroidism

Pheochromocytoma

Diabetes mellitus

Liver disease

Hyperaldosteronism

Intracranial lesions (1 intracranial pressure)

High-salt diet (?)

Obesity

Chronic anemia (cats)

#### Other Diseases Associated with Hypertension in People\*

Acromegaly

Inappropriate antidiuretic hormone secretion

Hyperviscosity/erythrocytosis

Renin-secreting tumors

Hypercalcemia

Hypothyroidism with atherosclerosis

Hyperestrogenism

Coarctation of the aorta

Pregnancy

Central nervous system disease

that raise cardiac output (by increasing heart rate, stroke volume, and/or blood volume) or by those that increase vascular resistance. Arterial BP normally is maintained within narrow bounds by the actions of the autonomic nervous system (e.g., via arterial baroreceptors), various hormonal systems (e.g., the renin-angiotensin system [RAAS], aldosterone, vasopressin/antidiuretic hormone, and natriuretic peptides), blood volume regulation by the kidney, and other factors.

Modulation of these systems by various disease conditions can lead to chronic elevation of arterial BP. For example, hypertension can result from increased sympathetic nervous activity or responsiveness (e.g., hyperthyroidism, hyperadrenocorticism), increased catecholamine production (e.g., pheochromocytoma), or volume expansion caused by increased sodium retention (e.g., decreased glomerular filtration and reduced sodium excretion in renal failure, hyperaldosteronism, hyperadrenocorticism, acromegaly). RAAS activation, with subsequent salt and water retention and vasoconstriction, may result from intrarenal diseases (e.g., glomerulonephritis, chronic interstitial nephritis), enhanced production of angiotensinogen (e.g., hyperadrenocorticism), and extrarenal diseases that increase sympathetic nervous activity or interfere with renal perfusion (e.g., hyperthyroidism, renal artery obstruction). Impaired production of vasodilator substances (e.g., prostaglandins, kallikreins) and

Left ventricular hypertrophy (overt heart failure rare) Murmur or gallop sound Aortic dilation

Aortic dilation

Aneurysm or dissection rare

#### Other

**Epistaxis** 

effects related to secondary hyperparathyroidism may be involved in chronic renal failure.

High perfusion pressure can damage capillary beds. In most tissues capillary pressure is regulated by vasoconstriction of arterioles that feed the capillaries, although this control may be inadequate because of underlying organ disease. The continued arteriolar constriction secondary to chronic hypertension leads to hypertrophy and other vascular remodeling changes that can further increase vascular resistance. These structural changes and vascular spasm can cause capillary hypoxia, tissue damage, hemorrhage, and infarction, which can lead to organ dysfunction (Box 11-2).

Organs that are particularly vulnerable to damage resulting from chronic hypertension are the eye, kidney, heart, and brain. These structures are often referred to as *target-organs* or *end-organs*. In the eye hypertension often causes focal perivascular edema, hemorrhage, and ischemia, especially in the retina and choroid layers. Bullous or total retinal detachment is common. Hyphema, vitreal hemorrhage, and optic neuropathy can also occur. Renal glomerular hypertension

<sup>\*</sup>Essential hypertension is often associated with family history, high salt intake, smoking, or obesity.

occurs when afferent arteriolar autoregulation is disrupted. The resulting glomerular hyperfiltration can lead to glomerulosclerosis, renal tubular degeneration, and fibrosis. These changes contribute to renal function deterioration and increasing vascular resistance; thus chronic hypertension tends to perpetuate itself. Proteinuria is an important manifestation of renal damage and has been associated experimentally with severity of hypertension in cats and dogs. Blood pressure is not directly correlated with serum creatinine concentrations, and hypertension can develop prior to azotemia. Increased systemic arterial pressure and vascular resistance increase the afterload stress on the heart and stimulate left ventricular hypertrophy. Increased cerebral vascular pressure can promote edema formation, raise intracranial pressure, and cause hemorrhage.

#### **Clinical Features**

Clinically recognized arterial hypertension usually occurs in middle-aged to older dogs and cats, presumably because of the associated disease conditions. Cats with severe end-organ disease secondary to hypertension tend to be geriatric. Signs of hypertension relate either to underlying disease or to endorgan damage caused by the hypertension itself.

Ocular signs are the most common presenting issue, especially sudden blindness, which usually results from acute retinal hemorrhage or detachment. Although the retina may reattach, sight often does not return. Ocular fundic changes associated with hypertension include bullous to complete effusive retinal detachment, intraretinal edema, and hemorrhage. Vascular tortuosity, hyperreflective scars, retinal atrophy, papilledema, and perivasculitis are other signs. Hemorrhage in the anterior or posterior chamber, closed-angle glaucoma, and cornal ulceration may also occur.

Another common complaint is polyuria and polydipsia, which can be associated with renal disease, hyperadrenocorticism (in dogs), or hyperthyroidism (in cats). Furthermore, hypertension itself causes a so-called pressure diuresis. Epistaxis can result from vascular rupture in the nasal mucosa. Hypertensive encephalopathy resulting from edema and vascular lesions can cause lethargy, seizures, abnormal mentation, collapse, or other neurologic or nonspecific signs. Paresis and other focal defects can occur as a result of cerebrovascular accident (stroke) caused by hypertensive arteriolar spasm or hemorrhage.

A soft, systolic cardiac murmur is commonly heard on auscultation in animals with hypertension. A gallop sound may also be present, especially in cats. Clinical heart failure is uncommon.

#### Diagnosis

Blood pressure measurements are indicated not only when signs compatible with hypertension are found but also when a disease associated with hypertension is diagnosed. A diagnosis of arterial hypertension should be confirmed by measuring BP multiple times and on different days. A routine laboratory database (complete blood count [CBC]; serum biochemical profile; and urinalysis, with or without a urine

protein: creatinine ratio [UPC]) is indicated in all hypertensive patients. However, not all hypertensive patients with underlying chronic renal disease are azotemic. Other tests are done as needed to rule out possible underlying diseases or complications. These might include various endocrine tests, thoracic and abdominal radiographs, ultrasonography (including echocardiography), electrocardiography, ocular examination, and serologic tests.

Thoracic radiographs often reveal some degree of cardiomegaly in patients with chronic hypertension. Cats especially may have a prominent aortic arch and an undulating (wavy) appearance to the thoracic aorta, although these findings may not be exclusive to hypertension. Electrocardiographic (ECG) findings may suggest left atrial (LA) or left ventricular (LV) enlargement. Arrhythmias do not appear to be common.

Mild to moderate LV hypertrophy is seen on echocardiography in some cases, although often measurements are within normal reference range. LV wall and septal hypertrophy may be symmetric or asymmetric. Other echocardiographic findings may include mild LA enlargement and sometimes mitral or mild aortic regurgitation. Proximal aortic dilation is another echocardiographic finding in some animals with systemic hypertension. Nelson et al. (2002) found that almost all hypertensive cats, but not healthy older cats, had a ratio of proximal ascending aortic diameter: aortic valve annulus diameter of ≥1.25.

#### **BLOOD PRESSURE MEASUREMENT**

Several methods can be used to measure systemic arterial BP in the clinic. Calculating the average of several measurements (generally between three and five) in succession is recommended to increase accuracy. When readings differ widely, the highest and lowest are discarded and an average value from at least three readings is used. High pressures should be confirmed by repeated measurement sessions before a diagnosis of hypertension is made. Anxiety related to the clinical setting may falsely increase blood pressure in some animals (i.e., the "white-coat effect"). Using the least restraint possible in a quiet environment and allowing time (e.g., 5 to 15 minutes) for acclimatization is best for awake animals. Use of a consistent technique and cuff size is important.

#### **Direct Blood Pressure Measurement**

Arterial pressure is measured directly by a needle or catheter placed into an artery and connected to a pressure transducer. Direct arterial pressure measurement is considered the gold standard, but it requires greater technical skill; moreover, in awake animals the physical restraint and discomfort associated with arterial puncture may falsely increase BP. Direct arterial pressure measurement is more accurate than indirect methods in hypotensive animals.

For arterial pressure monitoring over a period of time, an indwelling arterial line is often the best approach. The dorsal metatarsal artery is commonly used for this technique. An electronic pressure monitor provides continuous measure-

ment of systolic and diastolic pressures and calculated mean pressure. With fluid-filled systems, the pressure transducer must be placed at the level of the patient's right atrium to prevent a false increase or decrease of the measured pressure related to the effects of gravity on the fluid within the connecting tubing. The use of wireless, telemetric blood pressure monitors for dogs is currently under investigation.

When occasional BP measurement is needed, a small-gauge needle attached directly to a pressure transducer may be used to puncture the dorsal metatarsal or femoral artery. To prevent hematoma formation, direct pressure should be applied to the arterial puncture site for several minutes after removing the catheter or needle used for BP measurement.

#### **Indirect Blood Pressure Measurement**

Several noninvasive methods are available to indirectly measure BP. These techniques involve the use of an inflatable cuff that is placed around a limb, usually the radial artery (most dogs) or brachial artery (small dogs and cats) or the median caudal artery of the tail to occlude blood flow. Controlled release of cuff pressure is monitored to detect the return of flow. Doppler ultrasonic flow detection and oscillometric methods are used most often. Both techniques produce measurements that correlate fairly well with direct BP measurement but are not exactly predictive of it. Indirect methods are most reliable in normotensive and hypertensive animals. The Doppler method has shown greater correlation with direct BP measurement in conscious cats compared with the oscillometric method. Other methods, such as auscultation and arterial palpation, are not recommended for estimating BP. The auscultatory method (used to detect Korotkoff sounds in people) is technically impractical because of the limb conformation of dogs and cats. Direct arterial palpation is not reliable for estimating BP because pulse strength depends on the pulse pressure (systolic minus diastolic arterial pressure), not the absolute level of systolic or mean pressure. Pulse strength is also influenced by body conformation and other factors.

Cuff size and placement. Human pediatric- and infant-size cuffs can be used for indirect BP measurement in dogs and cats. The cuff must be the correct size for the patient. The width of the inflatable balloon (bladder) within the cuff should be about 30% (especially for cats) to 40% (especially for dogs) of the circumference of the extremity it surrounds. The length of the balloon should cover at least 60% of this circumference. Some of the cuff inflation pressure goes toward tissue compression. Cuffs that are too narrow are more affected by this phenomenon and produce falsely increased pressure readings; cuffs that are too wide may underestimate BP. The cuff bladder should be centered over the target artery. Common cuff locations are midway between the elbow and carpus or in the tibial region; skeletal prominences are avoided. The cuff should encircle the limb snugly without being excessively tight. Tape (not just Velcro on the cuff) is used to secure the cuff in position.

**Oscillometric method.** The indirect oscillometric method uses an automated system for detecting and process-

ing cuff pressure oscillation signals. Veterinary models are available (e.g., Cardell Veterinary Blood Pressure Monitor, Sharn, Inc; Memoprint, S&B medVET). With these systems the flow occlusion cuff is inflated to a pressure above the systolic pressure and then slowly deflated in small pressure decrements. The microprocessor measures and averages the resulting pressure oscillations that are characteristic of systolic, diastolic, and/or mean pressures (depending on the system). Accurate results with oscillometric methods depend on careful adherence to the directions for use and an immobile subject. Because muscle contraction can produce oscillations, the limb used should not be bearing weight. At least five readings should be obtained; the lowest and highest are discarded, and the remaining measurements are averaged. The oscillometric method may be difficult to use effectively in small dogs and cats; underestimation of systolic BP is

**Doppler ultrasonic method.** This method employs the frequency change between emitted ultrasound and returning echoes (from moving blood cells or vessel wall) to detect blood flow in a superficial artery. This frequency change, the so-called Doppler shift, is converted to an audible signal. One system commonly used in animals is designed to determine systolic pressure by detecting blood cell flow (Ultrasonic Doppler Flow Detector, Model 811, Parks Medical Electronics, Inc).

Effective locations for pressure measurement include the dorsal metatarsal, palmar common digital (forelimb), and median caudal (tail) arteries. The probe is placed distal to the occluding cuff. A small area of hair is clipped over the artery for probe placement. Ultrasonic coupling gel is applied to the flat Doppler flow probe to obtain air-free contact with the skin. The probe is positioned so that a clear flow signal is heard; it must not be held so tightly that it occludes flow. The probe must remain still to minimize noise; it can be taped in place. A low volume setting on the Doppler unit or a headset is used to minimize patient anxiety caused by the loud audio signals.

The flow-occluding cuff is attached to a sphygmomanometer and inflated to about 20 to 30 mm Hg above the point at which arterial flow ceases and no audible signals are heard. The cuff is slowly deflated (by a few mm Hg per second). During deflation, characteristic pulsatile flow signals from blood cell (or arterial wall) motion return during systole. The systolic pressure is the pressure at which blood flow first recurs (indicated by brief swishing sounds). Sometimes a change in the flow sound from short and pulsatile to a longer, more continuous swishing can be detected as cuff pressure diminishes; the pressure at which this change occurs is an approximation of diastolic pressure. Doppler estimation of diastolic BP is less accurate because of its subjective nature. The change in flow sound is not always detectable, especially with small or stiff vessels. As with the oscillometric method, it may be difficult to obtain measurements in small or hypotensive animals with the Doppler method. Patient movement also interferes with measurement.

#### Treatment and Prognosis

Antihypertensive therapy is indicated for animals with severe hypertension and those with clinical signs presumed to be caused by hypertension. Measured BP in such animals is generally over 180/120 mm Hg. Although some cases constitute hypertensive emergencies that require immediate therapy and intensive monitoring (discussed in more detail later), most hypertensive animals can be managed more conservatively (Box 11-3). Gradual reduction in BP may be safer in patients with long-standing hypertension. Chronically high BP leads to vascular adaptations in the cerebral autoregulatory process; if BP is suddenly reduced, cerebral perfusion may be adversely affected. It is unclear whether all dogs and cats with moderate hypertension (e.g., repeatable systolic pressures of 160 to 180 mm Hg) benefit from specific antihypertensive treatment. Nevertheless, patients with high BP that persists after treatment for the primary disease, as well as those with evidence of end-organ damage, should be treated. The goal of therapy is to reduce the BP to below 150/95 mm Hg. The expense and time commitment required for long-term antihypertensive therapy and monitoring as well as the potential for adverse medication effects are considerations.

Several drugs are used as antihypertensive agents in dogs and cats (Table 11-1). Usually one drug is administered at a time, with initially low doses, and the animal is monitored to assess efficacy. It may take 2 or more weeks for a significant decrease in BP to be observed. The drugs used most often are angiotensin-converting enzyme inhibitors (ACEIs), the Ca<sup>++</sup>-blocker amlodipine, and β-adrenergic blockers. Therapy with a single agent is effective in some cases, whereas combination therapy may be needed for adequate BP control in others. An ACEI is recommended as the initial antihypertensive drug in dogs, and amlodipine in cats, unless hyperthyroidism is the underlying cause. For hyperthyroid-induced hypertension, atenolol or another β-blocker is used first.

Ancillary strategies may be helpful in patients with hypertension, although alone they are unlikely to markedly reduce BP. Moderate dietary salt reduction (e.g., ≤0.22% to 0.25%

BOX 11-3

Approach to the Patient with Hypertension

#### Suspect Hypertension or Disease Associated with Hypertension (see Box 11-2, text)

Measure BP (see text)

- Use quiet environment.
- Allow at least 5 to 10 minutes for patient to acclimate to environment (if animal is easily stressed, have owner present when possible).
- Measure limb circumference, and use appropriate-size cuff (use same cuff size for subsequent measurements as well).
- Use consistent measurement technique.
- Take at least five BP readings; discard highest and lowest, average the remaining readings.

Repeat BP measurements at other (one to three) times, preferably on different days, to confirm diagnosis of hypertension, except:

 If acute, hypertension-induced clinical signs (e.g., ocular hemorrhage, retinal detachment, neurologic signs) are present, begin therapy immediately (see p. 190; Table 11-1).

Screen for underlying disease(s) (see Box 11-1)

- Obtain CBC, serum biochemistry tests, urinalysis.
- Obtain other data depending on individual presentation: endocrine testing, thoracic and abdominal radiographs, ocular examination, ECG, echocardiography, other tests as indicated.

#### **If Hypertension Confirmed:**

Manage underlying disease(s).

Avoid drugs that can increase BP, if possible.

Use reduced-sodium or weight reduction diet if patient is

Begin initial antihypertensive drug therapy (see Table 11-1).

- Dogs: enalapril or other ACEL
- If pheochromocytoma suspected, see p. 190
- Nonhyperthyroid cats: amlodipine
- Hyperthyroid cats: atenolol or other β-blocker
- If emergent therapy needed, see p. 190

Provide client education about the patient's disease(s) and potential complications, medication and reevaluation schedules, potential adverse effects of medication(s), and dietary concerns.

#### Patient Reevaluation

Recheck BP in 1 to 2 weeks for clinically stable patients.

 Earlier reevaluation is advised for unstable patients, but full effects of antihypertensive drugs may not yet be realized.

Obtain other tests as individually indicated.

Decide whether to continue therapy as is or adjust dose (up or down).

Continue weekly to biweekly BP monitoring and underlying disease management.

 If BP control is not achieved after maximum dosage of initial agent, try alternative drug or combination therapy.

When BP (and underlying disease) is controlled, gradually increase time between recheck examinations.

- Recheck no less frequently than every 2 to 3 months because medication requirements may change.
- Recheck baseline lab data every 6 months or as individually indicated.

#### Drugs Used to Treat Hypertension

DRUG	DOG	CAT
ACEIs (see Chapter 3)		
Enalapril Benazepril Ramipril Captopril	0.5 mg/kg PO q24(-12)hr 0.25-0.5 mg/kg PO q24(-12)hr 0.125-0.25 mg/kg PO q24hr 0.5-2.0 mg/kg PO q8-12hr	0.25-0.5 mg/kg PO q24hr same — 0.5-1.25 mg/kg PO q12-24hr
Calcium Channel Blocker		
Amlodipine	0.1-0.3 (-0.5) mg/kg PO q24(-12)hr	0.625 mg/cat (or 0.1-0.2 mg/kg) PO q24(-12)hr
β-Adrenergic Blockers (see Chap	oter 4)	
Atenolol Propranolol	0.2-1.0 mg/kg PO q12-24hr (start low) 0.1-1.0 mg/kg PO q8hr (start low)	6.25-12.5 mg/cat PO q(12-)24hr 2.5-10 mg/cat PO q8-12hr
α <sub>1</sub> -Adrenergic Blockers		
Phenoxybenzamine Prazosin	0.2-1.5 mg/kg PO q(8-)12hr 0.05-0.2 mg/kg PO q8-12hr	0.2-0.5 mg/kg PO q12hr —
Diuretics (see Chapter 3)		
Furosemide Hydrochlorothiazide	0.5-3 mg/kg PO q8-24hr 1-4 mg/kg PO q12-24hr	0.5-2 mg/kg PO q12-24hr 1-2 mg/kg PO q12-24hr
Drugs for Hypertensive Crisis		
Hydralazine (see Chapter 3)	0.5-2.0 mg/kg PO q12h (titrate up to effect); or 0.2 mg/kg IV or IM, repeat q2h as needed	same
Nitroprusside (see Chapter 3)	0.5-1 μg/kg/min CRI (initial) to 5-15 μg/kg/min CRI	same
Enalaprilat Esmolol Propranolol Labetolol	0.2 mg/kg IV, repeat q1-2h as needed 50-75 μg/kg/min CRI 0.02 mg/kg (initial) to 0.1 mg/kg slow IV 0.25 mg/kg IV over 2 min, repeat up to total dose of 3.75 mg/kg, followed by CRI of 25 μg/kg/min	same same same
Acepromazine Phentolamine	0.05-0.1 mg/kg (up to 3 mg total) IV 0.02-0.1 mg/kg IV bolus, followed by CRI to effect	same same

ACEI, Angiotensin-converting enzyme inhibitor; PO, by mouth; IV. intravenous; CRI, constant rate infusion.

sodium on a dry matter basis) is advised for all cases. Although not expected to normalize BP by itself, it may enhance antihypertensive drug effectiveness. A high-salt diet may contribute to development of hypertension in some cats, although salt intake does not generally affect BP in normal cats. Conversely, neurohormonal activation and potassium excretion may be increased in cats with renal dysfunction that are fed a low-sodium diet. Weight reduction is usually advised for obese animals. It is prudent to avoid prescribing drugs that can potentiate vasoconstriction (e.g., phenylpropanolamine and other  $\alpha_1$ -adrenergic agonists). Glucocorticoids and progesterone derivatives should also be avoided when possible because steroid hormones can increase BP. A diuretic (thiazide or furosemide; see Chapter 3) may help by reducing blood volume in patients with volume expansion, but a diuretic alone is rarely effective. Diuretics are avoided or used only with caution in animals with renal disease because they can lead to dehydration and exacerbate azotemia. Serum potassium concentration should be monitored, especially in cats with chronic renal disease.

The ability to monitor BP is important when antihypertensive drugs are prescribed. Serial measurements are needed to assess treatment efficacy and prevent hypotension. Adverse effects of antihypertensive therapy usually relate to hypotension, manifested by lethargy or ataxia, and reduced appetite. Attaining initial BP control may take several weeks. Monitoring may be done every 1 to 2 weeks to assess the efficacy of antihypertensive treatment in non-urgent cases. Once satisfactory regulation is achieved, BP should be measured at least every 2 or 3 months. Some animals become refractory to therapy that was initially effective. Increased antihyper-

tensive dosage, adjunctive therapy, or a change of antihypertensive drug can be tried. Continued attention to the underlying disease process is important. Routine CBC, serum biochemistry profile, and urinalysis (with or without a UPC) are also recommended every 6 months. Decreasing the magnitude of proteinuria associated with hypertension is a desired treatment outcome.

The long-term prognosis for animals with hypertension is usually guarded because underlying disease processes tend to be severe and progressive. Therapy for some primary diseases can exacerbate hypertension or complicate its control. Fluid therapy, corticosteroids, and erythropoietin are examples. The degree of proteinuria appears to be a negative prognostic factor in cats with chronic renal disease.

#### ANTIHYPERTENSIVE DRUGS

The ACEIs (e.g., enalapril, benazepril) reduce angiotensin II production, thereby reducing vascular resistance and volume retention (see p. 63). These agents have been more effective in dogs, although their efficacy depends on the degree of RAAS activation underlying the hypertension. Cats with chronic kidney disease and hypertension often are not responsive to ACEIs. However, an ACEI may help protect against hypertensive renal damage by preferentially reducing efferent arteriolar constriction and reducing glomerular hypertension.

Amlodipine besylate is a long-acting dihydropyridine  $Ca^{++}$ -blocker that causes vasodilation without appreciable cardiac effects. It can be effective as a primary antihypertensive agent in cats and has a duration of effect of at least 24 hours. Amlodipine generally does not alter serum creatinine concentration or body weight in cats with chronic kidney disease. Mild hypokalemia should respond to oral potassium supplementation. The drug is usually dosed once daily and may be given with or without food. Administration q12h may be used in large cats or in those that do not respond sufficiently to the lower dose. Alternatively, a  $\beta$ -blocker or ACEI may be added for cats that do not respond adequately to amlodipine alone. Amlodipine tablets are difficult to split evenly but they can be compounded using lactose as a diluent.

Amlodipine also is effective in some dogs. A lower dose is tried initially and titrated upward as necessary over a period of days. Amlodipine's half-life is about 30 hours in dogs; maximal effects occur 4 to 7 days after initiating therapy. Oral bioavailability is high, and peak plasma concentrations are reached 3 to 8 hours after administration; plasma concentrations increase with chronic therapy. The drug undergoes hepatic metabolism, but there is not extensive first-pass elimination; caution is warranted when liver function is poor. The drug is excreted through the urine and feces. A Ca'-channel blocker used as adjunctive therapy with an ACEI in dogs may control BP while yielding a balanced effect on glomerular pressure and glomerular filtration rate (GFR) through equal dilation of afferent and efferent arterioles.

 $\beta$ -adrenergic blockers may reduce BP by decreasing heart rate, cardiac output, and renal renin release. Atenolol and propranolol have been used most often (see p. 89). A  $\beta$ -blocker is recommended for cats with hyperthyroid-induced hypertension. However,  $\beta$ -blockers are often ineffective when used as the sole antihypertensive agent in cats with renal disease.

 $\alpha_1$ -adrenergic antagonists oppose the vasoconstrictive effects of these  $\alpha$ -receptors. Their main use is for hypertension caused by pheochromocytoma. Phenoxybenzamine is a noncompetitive  $\alpha_1$ - and  $\alpha_2$ -blocker used most often for pheochromocytoma-induced hypertension. Treatment is initiated with a low dose that is titrated upward as necessary. The  $\alpha_1$ -blocker prazosin is another option for large dogs. After  $\alpha$ -blocker dosing is begun, adjunctive therapy with a  $\beta$ -blocker can help control reflex tachycardia or arrhythmias.

Hypotension is a potential adverse effect of antihypertensive drugs and is usually manifested as periods of lethargy or ataxia. Reduced appetite may be another adverse effect. Rebound hypertension can occur if antihypertensive therapy is suddenly discontinued. This is especially of concern when using  $\beta$ - or  $\alpha_2$ -blockers. If therapy with such agents is to be terminated, the dosage should be gradually tapered down.

#### HYPERTENSIVE EMERGENCY

Urgent antihypertensive therapy is indicated when new or progressive signs of severe hypertension are identified. Examples include acute retinal detachment and hemorrhage, encephalopathy, or other evidence of intracranial hemorrhage, acute renal failure, aortic ancurysm, and acute heart failure.

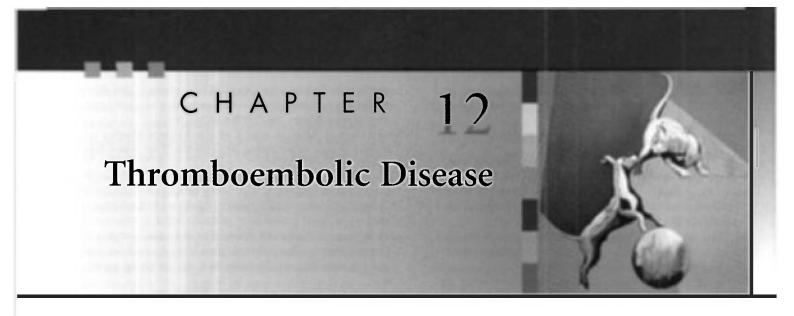

Direct-acting vasodilator agents generally produce faster reduction in BP (e.g., nitroprusside, hydralazine). Nitroprusside can be dosed to effect by constant intravenous (IV) infusion, but arterial pressure should be closely monitored to prevent hypotension (see Table 11-1). Hydralazine given intravenously or orally is an alternative, especially for dogs. Oral amlodipine can be effective in quickly reducing blood pressure in cats and has less risk of inducing hypotension. An IV  $\beta$ -blocker (propranolol, esmolol, or labetolol), ACEI (enalaprilat), or acepromazine (see Table 11-1) also can be used. One of these agents can be added to oral hydralazine therapy if that has not adequately reduced BP within 12 hours.

When hypertensive crisis is related to pheochromocytoma or other cause of catecholamine excess, the  $\alpha$ -blocker phentolamine is used IV (see Table 11-1) and titrated to effect. Addition of a  $\beta$ -blocker can help mitigate pheochromocytoma-induced tachyarrhythmias, but it should not be administered alone or before an  $\alpha$ -blocker is given. Use of a  $\beta$ -blocker as the sole agent in this setting leaves  $\alpha_1$ -receptors unopposed and is likely to exacerbate hypertension. Antihypertensive treatment is recommended for 2 to 3 weeks before surgery for pheochromocytoma excision, if possible. For inoperable pheochromocytoma, therapy is continued orally to prevent hypertensive emergencies.

# CHAPTER OUTLINE

GENERAL CONSIDERATIONS
PULMONARY THROMBOEMBOLISM
SYSTEMIC ARTERIAL THROMBOEMBOLISM IN CATS
Prophylaxis Against Arterial Thromboembolism
SYSTEMIC ARTERIAL THROMBOEMBOLISM IN DOGS
Prophylaxis against Arterial Thromboembolism
VENOUS THROMBOSIS

#### GENERAL CONSIDERATIONS

Thromboembolic (TE) disease involves either a locally formed (*in situ*) clot, an aggregation of platelets and other blood elements (thrombus), or a clot or other aggregate that breaks away from its origination site (embolus) and is carried downstream by blood flow. Both thrombi and emboli can partially or completely obstruct blood flow, either in a vessel or in the heart. TE disease can occur whenever normal hemostatic mechanisms are disturbed. Most clinically recognized TE events involve the distal aorta, pulmonary arteries, heart, or cranial vena cava. (For additional information on the pathogenesis of TE, see Chapter 87.)

The clinical sequelae of TE disease depend mainly on the size and location of the clot(s). These factors determine how much functional compromise occurs and in which organs and tissues. Acute, profound clinical signs result from some thrombolemboli. Others cause subclinical tissue damage and varying degrees of pathology. TE disease is sometimes suspected antemortem; in other cases it is discovered at necropsy (or not at all).

There is normally an interplay among the different factors that promote coagulation, inhibit coagulation, and promote fibrinolysis. A proper balance of these factors maintains blood fluidity and minimizes loss when vessels are damaged. Platelets, the vascular endothelium, proteins of the coagulation cascade, and the fibrinolytic system are all involved in normal hemostasis. Injury to the vascular endothelium

quickly induces several reactions that cause vasoconstriction, hemostatic plug formation, and attempts at vascular repair in order to prevent blood loss.

Intact endothelium normally produces factors with antiplatelet, anticoagulant, and also fibrinolytic effects. Antiplatelet substances include nitric oxide and prostacyclin. Nitric oxide inhibits platelet activation and promotes local vasodilation. Prostacyclin also inhibits platelet activation and aggregation, while mediating vascular smooth muscle relaxation. Anticoagulant substances synthesized by intact endothelium include thrombomodulin, protein S, and heparan sulfate. These substances inhibit the coagulation process in a number of ways.

Damaged endothelial cells promote thrombus formation. Although this reduces blood loss in the event of vascular laceration, in other settings TE disease results. Endothelial damage contributes to thrombus formation in several ways. For example, injured endothelial cells release endothelin, which promotes vasoconstriction and decreases local blood flow as well as tissue factor (thromboplastin), which activates the extrinsic pathway of the coagulation cascade.

Exposed subendothelial collagen and other substances stimulate platelet adherence and aggregation. This is followed by platelet activation. Activated platelets release a number of substances that further stimulate the process of platelet aggregation. Fibrinogen binds to surface glycoprotein (gp) IIb/IIIa receptors, which are expressed on activated platelets. Fibrinogen linkage forms a primary platelet plug, which then stabilizes as platelets contract and fibrinogen is converted to fibrin via the action of thrombin (factor IIa) produced by the coagulation cascade.

Both the intrinsic and extrinsic pathways of the coagulation cascade feed into the common pathway to produce thrombin (see Chapter 87). Tissue factor (released from monocytes and damaged cells) stimulates the extrinsic pathway by activating factor VII. The intrinsic pathway amplifies the process; it also modulates fibrinolysis. Thrombin converts fibrinogen into fibrin monomers. These polymerize to soluble fibrin, which then is cross-linked by the action of thrombin-activated factor XIII. This insoluble fibrin stabilizes the clot. Thrombin also stimulates further

platelet aggregation as well as contributes to negative feedback inhibition of clotting by interacting with thrombomodulin, proteins C and S, and antithrombin (AT).

After a thrombus forms, several mechanisms limit its extent and promote its breakdown. Thrombolysis requires plasmin. Its inactive precursor, plasminogen, is converted to plasmin by tissue plasminogen activator (t-PA) when fibrin is present. During activation of the coagulation cascade, t-PA is simultaneously released by endothelial cells. Several other substances also can act as plasminogen activators. Plasmin degrades fibrinogen and soluble (noncrosslinked) fibrin to yield fibrinogen/fibrin degradation products (FDPs). Plasmin also cleaves cross-linked fibrin in stabilized clots into large fragments (x-oligomers) that are further broken down into p-dimers and other fragments. p-dimers are produced only with active coagulation and subsequent fibrinolysis. There are also negative feedback constraints on fibrinolysis (e.g., plasminogen activator inhibitors, α2antiplasmin, thrombin-activated fibrinolytic factor). Defective fibrinolysis is thought to play a role in pathologic thrombosis.

Inhibition of platelet adherence and activation is important in preventing primary platelet plug formation. In addition, there are three main mechanisms that limit thrombus formation: AT, protein C, and the fibrinolytic system. AT is a small protein produced by the liver, which is responsible for most of the anticoagulant effect of plasma. AT, with its co-factor heparan sulfate, binds and inactivates thrombin; factors IXa, Xa, Xia, and XIIa; and kallikrein. Protein C, a vitamin K—dependent glycoprotein, also is involved in countering thrombosis.

Malfunction of one or more of these systems promotes thrombosis.

### **Pathophysiology**

TE disease is more likely when changes in normal hemostatic processes create conditions that favor clot formation or impair thrombolysis. Three general situations (so-called Virchow's triad) promote pathologic thrombosis: abnormal endothelial structure or function, slowed or static blood flow, and a hypercoagulable state (either from increased procoagulant substances or decreased anticoagulant or fibrinolytic substances). A number of common diseases produce such conditions (Box 12-1).

Diseases that induce severe or widespread endothelial injury also cause loss of normal endothelial antiplatelet, anti-coagulant, and fibrinolytic functions. Increased coagulability and platelet activation favor pathologic thrombosis. Injured endothelium also releases tissue factor as well as antifibrinolytic factors. Subendothelial tissue, exposed because of endothelial cell damage, promotes thrombosis by acting as a substrate for clot formation and stimulating platelet adherence and aggregation.

Systemic release of inflammatory cytokines (e.g., tumor necrosis factor [TNF], various interleukins, platelet activating factor, nitric oxide) can cause widespread endothelial injury, induce tissue factor expression, and also inhibit anti-

### BOX 12-1

Diseases Potentially Associated with Thromboembolism

#### **Endothelial Disruption**

Sepsis

Systemic inflammatory disease

Heartworm disease

Neoplasia

Massive trauma

Shock

Intravenous catheterization

Injection of irritating substance

Reperfusion injury

Atherosclerosis

Arteriosclerosis

Hyperhomocysteinemia

#### **Abnormal Blood Flow**

Vascular obstruction (e.g., mass lesion, adult heartworms, catheter or other device)

Heart disease

Cardiomyopathy (especially in cats)

Endocarditis

Congestive heart failure

Shock

Hypovolemia/dehydration

Prolonged recumbency

Hyperviscosity (e.g., polycythemia, leukemia, hyperglobulinemia)

Hypoviscosity (anemia)

Anatomic abnormality (e.g., aneurysm, A-V fistula)

#### Increased Coagulability

Glomerular disease/protein-losing nephropathy

Hyperadrenocorticism

Immune-mediated hemolytic anemia (+/- thrombocytopenia)

**Pancreatitis** 

Protein-losing enteropathy

Sepsis/infection

Neoplasia

Disseminated intravascular coagulation

Heart disease

coagulant mechanisms. This occurs with sepsis and likely other systemic inflammatory conditions as well. Neoplastic invasion, vascular disruption resulting from other disease, and postischemic injury also induce endothelial damage. Mechanical trauma to the vascular endothelium (as with catheterization) can also precipitate TE disease, especially when other predisposing conditions exist. Pulmonary artery endothelial injury resulting from heartworm disease (HWD) is well known (see Chapter 10). The inflammatory reaction to dead or dying worms and worm fragments exacerbates the endothelial damage and prothrombotic conditions.

Stagnant blood flow promotes thrombosis by impeding the dilution and clearance of coagulation factors. Poor flow can promote local tissue hypoxia and endothelial injury as well. Abnormal turbulence has also been associated with thrombus formation. Turbulence can mechanically injure the endothelial surface.

Hypercoagulability may develop secondary to various systemic diseases in dogs and cats; multiple mechanisms are thought to be involved. Nevertheless, thrombus formation in such cases may also depend on altered endothelial integrity or blood flow. AT deficiency is a common cause of hypercoagulability. Excessive loss, increased consumption, or possibly inadequate hepatic synthesis leads to AT deficiency. Decreased protein C activity and other mechanisms may also contribute to hypercoagulability.

Increased platelet aggregability has been associated with neoplasia, some heart diseases, diabetes mellitus, and nephrotic syndrome in some animals. Thrombocytosis alone, without an increase in platelet aggregability, is not thought to increase the risk for thrombosis.

Defective fibrinolysis can promote pathologic thrombosis by preventing efficient breakdown of physiologic clots. This can result from either reduced levels of fibrinolytic substances (e.g., t-PA, plasminogen, urokinase) or increased production of plasminogen activator inhibitors; the latter is a major mechanism of TE disease in humans with hypertension.

Pancreatitis, shock, trauma, sepsis, neoplasia, severe hepatopathy, heatstroke, immune-mediated disease, and other conditions can lead to gross thrombosis as well as disseminated intravascular coagulopathy (DIC). DIC involves massive activation of thrombin and plasmin, with generalized consumption of coagulation factors and platelets. DIC produces extensive thrombosis as well as hemorrhage in the microcirculation, resulting in widespread tissue ischemia and multiorgan failure.

Protein-losing nephropathy (resulting from glomerulo-nephritis, renal amyloid deposition, or hypertensive injury) can lead to marked AT deficiency. Because of its small size, AT is lost through damaged glomeruli more easily than most procoagulant proteins, which predisposes to thrombosis. Protein-losing enteropathies also cause AT deficiency, but concurrent loss of larger proteins tends to maintain a balance between procoagulant and anticoagulant factors. Other factors also may contribute to TE disease in animals with protein-losing nephropathies, such as increased platelet aggregation secondary to hypoalbuminemia.

Thrombosis associated with immune-mediated hemolytic anemia (IMHA) is also thought to be multifactorial, with the systemic inflammatory (immune-mediated) response playing a large role. Thrombocytopenia, hyperbilirubinemia, and hypoalbuminemia have been identified as risk factors for TE disease. The role of high-dose corticosteroid therapy in pathologic thrombosis is unclear. However, TE disease is relatively common in animals receiving exogenous corticosteroids and in those with hyperadrenocorticism (see next paragraph). Other predisposing factors are usually concurrent in these cases as well.

TE disease occurs in some dogs with spontaneous hyperadrenocorticism. This endocrinopathy has been associated

with decreased fibrinolysis (resulting from increased plasminogen activator inhibitor [PAI] activity) and high levels of several coagulation factors. Diabetes mellitus is occasionally associated with TE disease in dogs. Platelet hyperaggregability and possibly hypofibrinolysis are thought to be involved. Occasionally, a patient with clinically relevant TE disease does not have any detectable abnormality that can result in hypercoagulability (e.g., Greyhounds with aortic TE disease not associated with detectable hemostatic or cardiovascular abnormalities). Cats with myocardial disease (see Chapter 8) are at risk for intracardiac thrombus formation and subsequent arterial embolization. The mechanisms involved probably relate to poor intracardiac blood flow (especially within the left atrium), altered blood coagulability, local tissue or blood vessel injury, or a combination of these. Increased platelet reactivity occurs in some of these cats. Abnormal turbulence may be a factor when mitral regurgitation occurs. DIC may accompany thromboembolism. Some cats with TE disease have decreased plasma arginine and vitamin B<sub>6</sub> and B<sub>12</sub> concentrations; hyperhomocysteinemia may be a factor in some cases. Hyperhomocysteinemia and low plasma vitamin B concentrations are risk factors for thromboembolism in people. It is not known if hypercoagulability induced by a genetic abnormality exists in some cats, as it does in people.

#### PULMONARY THROMBOEMBOLISM

Pulmonary thromboemboli in dogs are associated with HWD, other heart diseases, immune-mediated hemolytic anemia (IMHA), neoplasia, DIC, sepsis, hyperadrenocorticism, nephrotic syndrome, pancreatitis, trauma, hypothyroidism, and right atrial thrombus related to infection.

Pulmonary TE disease appears to be rare in cats compared with dogs, except in those with HWD. Nevertheless, pulmonary TE disease has been associated with a variety of systemic and inflammatory disorders in cats, including neoplasia, HWD, anemia (probably immune mediated), pancreatitis, glomerulonephritis, encephalitis, pneumonia, heart disease, sepsis, glucocorticoid administration, protein-losing enteropathy, and hepatic lipidosis.

Pulmonary TE disease that causes pulmonary hypertension variably produces right ventricular enlargement and hypertrophy, interventricular septal flattening, and high tricuspid regurgitation jet velocities. Sometimes a clot is identified within the pulmonary artery or right atrium.

## SYSTEMIC ARTERIAL THROMBOEMBOLISM IN CATS

The most common cause for arterial TE disease in cats is cardiomyopathy (see Chapter 8). Thrombi initially form in the left heart and can become quite large. Although some remain in the heart (usually the left atrial [LA] appendage; see Figure 8-6), others embolize to the distal aorta or, less often, other sites. Marked LA enlargement may magnify the risk for thromboembolus formation, but this is controversial. Neoplastic and systemic inflammatory disease are sometimes associated with systemic thromboemboli in cats. Hyperthyroidism may be a risk factor for TE disease in cats independent of its cardiac effects. In some cases, no predisposing condition is identified.

Systemic arterial emboli usually lodge at the aortic trifurcation (so-called saddle thrombus; Figure 12-1), but iliac, femoral, renal, brachial, and other arteries can be affected depending on embolus size and flow path. Besides obstructing flow in the affected artery, thromboemboli release vasoactive substances that induce vasoconstriction and compromise collateral blood flow development around the obstructed vessel. Tissue ischemia results and causes further damage and inflammation. An ischemic neuromyopathy occurs in the affected limb(s), with peripheral nerve dysfunction and degeneration as well as pathologic changes in associated muscle tissue.

Coronary thromboembolism with myocardial necrosis has occurred in cats with cardiac disease, especially severe hypertrophic cardiomyopathy or infective endocarditis, as well as from carcinoma emboli.

#### **Clinical Features**

Arterial TE disease in cats usually causes acute and dramatic clinical signs secondary to tissue ischemia (Fig. 12-2). Male cats are at higher risk for thromboembolism, but this gender bias appears to be related to the prevalence of hypertrophic cardiomyopathy. Distal aortic embolization occurs in most cases. However, the clinical findings depend on the area embolized as well as the extent and duration of arterial blockage.

FIG 12-1

Postmortem image with opened distal aorta, from a cat with cardiomyopathy. A thromboembolus (just left of the forceps tip) is lodged at the aortic trifurcation. The rear limbs are to the left in the image; cranial is to the right.

Signs of pain and poor systemic perfusion are usually present. Hypothermia and azotemia are common. A cardiac murmur, gallop sound, or arrhythmia is often identified, but these signs are not always evident even with underlying heart disease. Clinical signs of heart disease before the TE event are often absent. Tachypnea and open-mouth breathing are common in cats with acute arterial embolization, despite the absence of overt congestive heart failure (CHF). These signs may represent a pain response, although increased pulmonary venous pressure could be involved. Thoracic radiographs should be obtained as soon as possible because it is important to determine whether pulmonary edema underlies the respiratory signs.

Acute hindlimb paresis without palpable femoral pulses is typical. Common clinical findings are summarized in Box 12-2. Motor function in the rear limbs is minimal to absent in most cases, although the cat is usually able to flex and extend the hips. Sensation to the lower limbs is poor. One side may show greater deficits than the other. Emboli are occasionally small enough to lodge more distally in only one limb, which causes paresis of the lower limb alone. Embolization of a brachial artery produces (usually right) forelimb monoparesis. Intermittent claudication (see p. 201) occurs rarely. Thromboemboli within the renal, mesenteric, or pulmonary arterial circulation may result in failure of these organs and death. Emboli to the brain could induce seizures or various neurological deficits.

#### **Diagnosis**

Thoracic radiography is used to screen for cardiopulmonary abnormalities such as evidence for heart failure or other disease associated with thromboemboli (e.g., glomerulone-phritis, neoplasia, HWD). Most cats with arterial TE disease have some degree of cardiomegaly (especially LA enlargement) when cardiomyopathy is the underlying cause. Signs of heart failure include dilated pulmonary veins, pulmonary edema, or pleural effusion. A few affected cats have no radiographic evidence of cardiomegaly.

Echocardiography delineates the type of myocardial disease and may reveal the presence of an intracardiac thrombus (see Figure 8-6). The most common site for intracardiac thrombi is the left auricular appendage. Most cats with arterial TE disease associated with cardiomyopathy have some degree of LA enlargement. An LA dimension of >20 mm (measured from the two-dimensional long-axis four-chamber view) may increase the risk for TE disease, although more than half of aortic TE disease cases in one study had a smaller left atrium (Smith, 2003). If echocardiography is unavailable, nonselective angiocardiography can help define the nature of underlying cardiac disease and determine the location and extent of the thromboembolism.

Cats with arterial thromboembolism often have azotemia. This can be prerenal, resulting from poor systemic perfusion or dehydration; primary renal, resulting from embolization of the renal arteries or preexisting kidney disease; or a combination of both. Metabolic acidosis, DIC, electrolyte abnormalities (especially low serum sodium, calcium, potassium,

FIG 12-2

**A,** Cat with thromboembolism to the distal aorta. The left rear limb was dragged behind as the cat tried to walk; there was slightly better function in the right rear. **B,** The pads of the left rear paw (right side of image) in this cat were paler as well as cooler compared with the left forepaw (left side of image).

## BOX 12-2

#### Common Clinical Findings in Cats with Systemic Arterial Thromboembolism

Acute limb paresis

Posterior paresis

Monoparesis

±Intermittent claudication

Characteristics of affected limb(s)

Painful

Cool distal limbs

Pale footpads

Cyanotic nailbeds

Absent arterial pulse

Contracture of affected muscles (especially gastrocnemius

and cranial tibial)

Tachypnea/dyspnea

Rule out congestive heart failure versus pain or other

pulmonary disease Vocalization (pain and distress)

Hypothermia

Anorexia

Lethargy/weakness

Signs of heart disease (inconsistent)

Systolic murmur

Gallop sounds

Arrhythmias

Cardiomegaly

Signs of congestive heart failure

Pulmonary edema

Effusions

Hematologic and biochemical abnormalities

Azotemia

Increased alanine aminotransferase activity

Increased aspartate aminotransferase activity

Increased lactate dehydrogenase activity

Increased creatine kinase activity

Hyperglycemia (stress)

Lymphopenia (stress)

Disseminated intravascular coagulation

and elevated phosphorus), and stress hyperglycemia are common. Hyperkalemia may develop secondary to ischemic muscle damage and reperfusion. Skeletal muscle damage and necrosis are accompanied by elevations of alanine aminotransferase and aspartate aminotransferase activities, beginning within 12 hours of the TE event and peaking by 36 hours. Widespread muscle injury causes lactate dehydrogenase and creatine kinase activities to be increased soon after the event; elevations in these enzyme activities may persist for weeks. Metabolic acidosis, DIC, and hyperkalemia may also be present secondary to ischemic muscle damage and reperfusion. Cats with arterial TE disease usually have a normal coagulation profile.

Other causes of acute posterior paresis to be considered include intervertebral disk disease, spinal neoplasia (e.g., lymphoma), trauma, fibrocartilaginous infarction, diabetic neuropathy, and possibly myasthenia gravis.

# **Treatment and Prognosis**

The goals of treatment are to manage concurrent CHF and arrhythmias (if present), prevent extension of the embolus and formation of additional thrombi, promote collateral circulation, and provide supportive care (Box 12-3). The treatment of heart failure is outlined in Chapter 8 and Box 8-1. Propranolol is discouraged in cats with cardiomyopathy and arterial thromboembolism because its nonselective

BOX 12-3

#### Therapy for Thromboembolic Disease

Initial diagnostic tests

Complete physical examination and history
Hemogram, serum biochemical profile, urinalysis
Thoracic radiographs (rule out signs of congestive heart
failure, other infiltrates, pleural effusion)

Coagulation and D-dimer tests, if possible

Analgesia as needed (especially for systemic arterial thromboembolism)

#### Morphine

- Dog: 0.5-2.0 mg/kg administered intramuscularly, subcutaneously q3-5h; 0.05-0.4 mg/kg administered intravenously q3-5h
- Cat: 0.05-0.2 mg/kg administered intramuscularly, subcutaneously q3-4h (dysphoria occurs in some cats)

Oxymorphone or hydromorphone

- Dog: 0.05-0.2 mg/kg administered intramuscularly, intravenously, subcutaneously q2-4h
- Cat: 0.05-0.2 mg/kg administered intramuscularly, intravenously, subcutaneously q2-4h

#### Butorphanol

- Dog: 0.2-2.0 mg/kg administered intramuscularly, intravenously, subcutaneously q1-4h
- Cat: 0.2-1.0 mg/kg administered intramuscularly (cranial lumbar area), intravenously, subcutaneously q1-4h

#### Buprenorphine

- Dog: 0.005-0.02 mg/kg administered intramuscularly, intravenously, subcutaneously q6-8h
- Cat: 0.005-0.02 mg/kg administered intramuscularly, intravenously, subcutaneously q6-8h; can give by mouth for transmucosal absorption

#### Supportive care

Provide supplemental O<sub>2</sub> if respiratory signs exist.

Administer intravenous fluid as indicated (if not in congestive heart failure).

Monitor for and correct azotemia and electrolyte abnormalities.

Manage congestive heart failure if present (see Chapters 3.8).

Provide external warming if hypothermia persists after rehydration.

Identify and manage underlying disease(s).

Provide nutritional support if anorexia persists.

Further diagnostic testing

Complete cardiac evaluation, including echocardiogram Other tests as indicated (based on initial findings and cardiac exam) to rule out predisposing conditions

Prevention of extension of existing clot and new thromboembolic events

Antiplatelet therapy

#### • Áspirin

- Dog: 0.5 mg/kg by mouth q12h
- Cat: 81 mg/cat by mouth 2-3 times a week; low-dose, 5 mg/cat q72h (see text)

#### Clopidogrel

- Dog: 2-4 mg/kg by mouth q24h (dose not well-established)
- Cat: 18.75 mg/cat by mouth q24h (dose not wellestablished)

### Anticoagulant therapy

#### Sodium heparin

- Dog: 200-250 IU/kg administered intravenously, followed by 200-300 IU/kg administered subcutaneously q6-8h for 2-4 days or as needed
- Cat: same

#### Dalteparin sodium

- Dog: same as cat? (see text)
- Cat: 150 U/kg administered subcutaneously q4h? (see text)

#### • Enoxaparin

- Dog: same as cat?
- Cat: 1.5 mg/kg administered subcutaneously q6h? (see text)

Thrombolytic therapy (pursue only with caution, see text)

#### Streptokinase

- Dog: 90,000 IU infused intravenously over 20 to 30 minutes, then at 45,000 IU/h for 3 (or more) hours (see text)
- Cat: same

#### rt-PA

- Dog: 1 mg/kg bolus IV q1h for 10 doses (see text)
- Cat: 0.25-1 mg/kg/h (up to a total of 1-10 mg/kg) administered intravenously (see text)

 $\beta$ -blocking effect may contribute to peripheral vasoconstriction from unopposed  $\alpha$ -receptors, and the drug has no antithrombotic effects at clinical doses.

An analgesic is recommended, especially for the first 24 to 36 hours, because this is a painful condition. Butorphanol (0.15 to 0.5 mg/kg, administered intramuscularly into the cranial lumbar area or subcutaneously q1-3h) has been recommended, especially for the first 24 to 36 hours after the embolic event. Low-dose morphine (0.1 to 0.3 mg/kg q3-6h, administered intramuscularly or subcutaneously) could be considered, but some cats experience dysphoria. A fentanyl patch (25 µg/h size) applied to a shaved area of skin could

be used to help alleviate pain for up to 3 days, but because it takes about 12 hours to become effective, another analgesic is used simultaneously during this initial period. Respiratory depression and reduced gastrointestinal (GI) motility are potential side effects.

Acepromazine is not recommended for animals with arterial TE disease, despite its α-adrenergic receptor–blocking effects. Improved collateral flow has not been documented, and hypotension and exacerbation of dynamic ventricular outflow obstruction (in cats with hypertrophic obstructive cardiomyopathy) are potential adverse effects. Other supportive care is given to improve and maintain adequate

tissue perfusion, minimize further endothelial damage and blood stasis, and optimize organ function as well as to allow time for collateral circulation development.

Antiplatelet and anticoagulant therapies are used to reduce platelet aggregation and growth of existing thrombi. Although fibrinolytic therapy is used in some cases, dosage uncertainties, the need for intensive care, and the potential for serious complications stemming from reperfusion injury limit its use.

Aspirin (acetylsalicylic acid) is used commonly to block platelet activation and aggregation in patients with, or at risk for, TE disease. Aspirin irreversibly inhibits cyclooxygenase, which reduces prostaglandin and thromboxane A2 synthesis and therefore subsequent platelet aggregation, serotonin release, and vasoconstriction. Because platelets cannot synthesize additional cyclooxygenase, this reduction of procoagulant prostaglandins and thromboxane persists for the platelet's life span (7 to 10 days). Endothelial production of prostacyclin (also via the cyclooxygenase pathway) is reduced by aspirin but only transiently as endothelial cells synthesize additional cyclooxygenase. Aspirin's benefit may relate more to in situ thrombus formation; efficacy in acute arterial thromboembolism is unknown. Adverse effects of aspirin tend to be mild and uncommon, but the optimal dose is unclear. Cats lack an enzyme (glucuronyl transferase) that is needed to metabolize aspirin, so less frequent dosing is required compared with dogs. In cats with experimental aortic thrombosis, 10 to 25 mg/kg (1.25 grains/cat) given by mouth once every (2 to) 3 days inhibited platelet aggregation and improved collateral circulation. However, low-dose aspirin (5 mg/cat q72h) has also been used with fewer GI adverse effects, although its efficacy in preventing TE events is unknown. Aspirin therapy is started when the patient is able to take food and oral medications.

Other antiplatelet drugs are being studied. The thienopyridines inhibit adenosine diphosphate (ADP)-binding at platelet receptors and subsequent ADP-mediated platelet aggregation. Clopidogrel (Plavix; 18.75 mg/cat PO q24h) appears to have significant antiplatelet effects; daily dosing may be possible.

Heparin is indicated to limit extension of existing thrombi and prevent further TE episodes; it does not promote thrombolysis. Unfractionated heparin and a number of low-molecular-weight heparin (LMWH) products are available. Heparin's main anticoagulant effect is produced through AT activation, which in turn inhibits factors IX, X, XI, and XII and thrombin. Unfractionated heparin binds thrombin as well as AT. Heparin also stimulates release of tissue factor inhibitors from vascular sites, which helps reduce (extrinsic) coagulation cascade activation. Optimal dosing protocols for animals are not known. Unfractionated heparin is usually given as an initial intravenous (IV) bolus followed by subcutaneous (SC) injections (see Box 12-3). Heparin is not given IM because of the risk for hemorrhage at the injection site. Heparin doses (from 75 to 500 U/kg) have been used with uncertain efficacy. An initial IV dose of 200 IU/kg, followed by 150 to 200 IU/kg administered subcutaneously q6-8h for 2 to 4 days is one protocol. Monitoring the patient's activated partial thromboplastin time (aPTT) is recommended, although results may not accurately predict serum heparin concentrations. Pretreatment coagulation testing is done for comparison, and the goal is to prolong the aPTT to 1.5 to 2.5 times baseline. Activated clotting time is not recommended to monitor heparin therapy. Hemorrhage is the major complication. Protamine sulfate can be used to counteract heparin-induced bleeding. However, an overdose of protamine can paradoxically cause irreversible hemorrhage. Dosage guidelines for protamine sulfate are as follows: 1 mg/100 U of heparin is given if the heparin was given within the previous 60 minutes; 0.5 mg/100 U of heparin is given if the heparin was given more than 1 but less than 2 hours earlier; and 0.25 mg/100 U of heparin is given if more than 2 hours have elapsed since heparin was administered. Fresh frozen plasma may be needed to replenish AT. Heparin treatment is continued until the patient is stable and has been on antiplatelet therapy for a few days.

LMWH is a safer alternative to unfractionated heparin. LMWH products are a diverse group of depolymerized heparin that vary in size, structure, and pharmacokinetics. Their smaller size prevents simultaneous binding to thrombin and AT. LMWH products have more effect against factor Xa through their inactivation of AT. Because they have minimal ability to inhibit thrombin, they are less likely to cause bleeding. LMWH products have greater bioavailability and a longer half-life than unfractionated heparin when given subcutaneously because of lesser binding to plasma proteins as well as endothelial cells and macrophages. However, LMWH products do not markedly affect coagulation times, so monitoring aPTT is generally not necessary. LMWH effect can be monitored indirectly by anti-Xa activity. Optimal anti-Xa activity level in cats is not known; the target range in people is reported as 0.5 to 1.0 U/ml, although 0.3 to 0.6 U/ml has also been used. The LMWH products have differences in biological and clinical effects and are not interchangeable. The most effective dosage for the various LMWH products is not clearly established in dogs and cats. Commonly used dosages of dalteparin sodium (Fragmin; 100-150 U/kg administereed subcutaneously q8-24h) and enoxaparin (Lovenox; 1 mg/kg administered subcutaneously q12-24h) were extrapolated from human use. However, according to a recent study (Alwood et al., 2007), these doses do not produce a (human) target level of anti-Xa activity in cats. Although enoxaparin produced anti-Xa activity close to this level at 4 hours postdose, activity was undetectable 8 hours later. On the basis of this study, the predicted optimal dose and dosing interval to maintain anti-Xa activity within the (human) therapeutic range in normal cats are as follows: dalteparin, 150 U/kg administered subcutaneously q4h; and enoxaparin, 1.5 mg/kg administered subcutaneously q6h. The optimal therapeutic range in cats as well as the most effective dosage in sick cats are not yet known.

Drugs used to promote clot lysis include streptokinase and human recombinant tissue plasminogen activator (rt-PA). These agents increase conversion of plasminogen to plasmin to facilitate fibrinolysis. Veterinary experience with these agents is quite limited. Although they effectively break down clots, complications related to reperfusion injury and hemorrhage, the high mortality rate, the cost of therapy, the intensive care required, and the lack of clearly established dosing protocols have prevented their widespread use. Furthermore, a clear survival advantage has not been shown. If used, this therapy is best instituted within 3 to 4 hours of vascular occlusion. An intensive care setting, including continuous serum potassium concentration (or electrocardiographic [ECG]) monitoring to detect reperfusion-induced hyperkalemia, is recommended.

Streptokinase is a nonspecific plasminogen activator that promotes the breakdown of fibrin as well as fibrinogen. This action leads to the degradation of fibrin within thrombi and clot lysis but also potentially leads to systemic fibrinolysis, coagulopathy, and bleeding. Streptokinase also degrades factors V, VIII, and prothrombin. Although its half-life is about 30 minutes, fibrinogen depletion continues for much longer. Streptokinase has been used with variable success in a small number of dogs with arterial TE disease. The reported protocol is 90,000 IU of IV streptokinase infused over 20 to 30 minutes, then at a rate of 45,000 IU/hour for 3 (to 8) hours. Dilution of 250,000 IU into 5 ml saline, then into 50 ml to yield 5000 U/ml for infusion with a syringe pump has been suggested for cats. Adverse effects are minor in some cases, and bleeding may respond to discontinuing streptokinase. However, there is a risk for serious hemorrhage, and the mortality rate in clinical cases is high. Acute hyperkalemia (secondary to thrombolysis and reperfusion injury), metabolic acidosis, bleeding, and other complications are thought to be responsible for causing death. Streptokinase can increase platelet aggregability and induce platelet dysfunction. It is unclear if lower doses would be effective with fewer complications. Streptokinase combined with heparin therapy can increase the risk of hemorrhage, especially when coagulation times are increased. Streptokinase is potentially antigenic because it is produced by βhemolytic streptococci. No survival benefit has been shown for streptokinase therapy compared with conventional (i.e., aspirin and heparin) treatment in cats.

rt-PA is a single-chain polypeptide serine protease with a higher specificity for fibrin within thrombi and a low affinity for circulating plasminogen. Although the risk of hemorrhage is less than with streptokinase, there is the potential for serious bleeding as well as other side effects. rt-PA is also potentially antigenic in animals because it is a human protein. Like streptokinase, rt-PA induces platelet dysfunction but not hyperaggregability. Experience with rt-PA is very limited, and the optimal dosage is not known. An IV dose of 0.25 to 1 mg/kg/h up to a total of 1 to 10 mg/kg was used in a small number of cats; although signs of reperfusion occurred, the mortality rate was high. The cause of death in most cats was attributed to reperfusion (hyperkalemia, metabolic acidosis) and hemorrhage, although CHF and arrhythmias were also involved.

Surgical clot removal is generally not advised in cats. The surgical risk is high, and significant neuromuscular ischemic injury is likely to have already occurred by the time of surgery. Clot removal using an embolectomy catheter has not been very effective in cats.

In general, the prognosis is poor in cats with arterial TE disease. Historically, only a third of cats survive the initial episode. However, survival statistics improve when cats euthanized without therapy are excluded or when only cases from recent years are analyzed. Survival is better if only one limb is involved and/or if some motor function is preserved at presentation. Hypothermia and CHF at presentation are both associated with poor survival in cats. Other negative factors may include hyperphosphatemia, progressive hyperkalemia or azotemia, progressive limb injury (continued muscle contracture after 2 to 3 days, necrosis), severe LA enlargement, presence of intracardiac thrombi or spontaneous contrast ("swirling smoke") on echocardiogram, DIC, and history of thromboembolism.

Barring complications, limb function should begin to return within 1 to 2 weeks. Some cats become clinically normal within 1 to 2 months, although residual deficits may persist for a variable time. Tissue necrosis may require wound management and skin grafting. Permanent limb deformity develops in some cats, and amputation is occasionally necessary. Repeated events are common. Significant embolization of the kidneys, intestines, or other organs carries a grave prognosis.

# PROPHYLAXIS AGAINST ARTERIAL THROMBOEMBOLISM

Prophylactic therapy with an antiplatelet or anticoagulant drug is commonly used in animals thought to be at increased risk for TE disease. These include cats with cardiomyopathy (especially those with marked LA enlargement, echocardiographic evidence for intracardiac spontaneous contrast or thrombus, or a previous TE event) and animals with sepsis, IMHA, severe pancreatitis, or other procoagulant conditions. However, the efficacy of TE prophylaxis is unknown, and a strategy that consistently prevents thromboembolism is not yet identified.

Drugs used for arterial TE prophylaxis include aspirin, clopidogrel, warfarin (coumadin), and LMWH. Aspirin and clopidogrel present a low risk for serious hemorrhage and require less monitoring compared with warfarin. Adverse GI effects (e.g., vomiting, inappetence, ulceration, hematemesis) occur in some animals. Buffered aspirin formulation or an aspirin-Maalox combination product may be helpful. Low-dose aspirin (5 mg/cat every third day) has been advocated in cats. Although adverse effects are unlikely with this dose, it is not known whether antiplatelet effectiveness is compromised. Warfarin (discussed in more detail later) is associated with greater expense and a higher rate of fatal hemorrhage. No survival benefit has been shown for warfarin compared with aspirin in cats. In some reports, recurrent thromboembolism occurred in almost half of cats treated with warfarin. Clopidogrel or

LMWH prophylaxis may be more efficacious, with less risk of hemorrhage, but more experience with this therapy is needed. Recurrent TE events occurred in 20% of cats in one study (Smith, 2004). LMWH is expensive and must be given by daily SC injection, but some owners are motivated to do this. In cats without thrombocytopenia, aspirin may be used concurrently. Diltiazem, at clinical doses, does not appear to have significant platelet-inhibiting effects.

Warfarin inhibits the enzyme (vitamin K epoxide reductase) responsible for activating the vitamin K-dependent factors (II, VII, IX, and X), as well as proteins C and S. Initial warfarin treatment causes transient hypercoagulability because anticoagulant proteins have a shorter half-life than most procoagulant factors. Therefore heparin (e.g., 100 IU/ kg administered subcutaneously q8h) is given for 2 to 4 days after warfarin is initiated. There is wide variability in dose response and potential for serious bleeding, even in cats that are monitored closely. Warfarin is highly protein-bound; concurrent use of other protein-bound drugs or change in serum protein concentration can markedly alter the anticoagulant effect. Bleeding may be manifested as weakness, lethargy, or pallor rather than overt hemorrhage. A baseline coagulation profile and platelet count are obtained, and aspirin discontinued, before beginning treatment. The usual initial warfarin dose is 0.25 to 0.5 mg (total dose) administered orally q24-48h in cats. Uneven distribution of drug within the tablets is reported, so compounding rather than administering tablet fragments is recommended. Drug administration and blood sampling times should be consistent.

The dose is adjusted either on the basis of prothrombin time (PT) or the international normalization ratio (INR). The INR is a more precise method that has been recommended to prevent problems related to variation in commercial PT assays. The INR is calculated by dividing the animal's PT by the control PT and raising the quotient to the power of the international sensitivity index (ISI) of the thromboplastin used in the assay, or INR = (animal PT/ control PT) ISI. The ISI is provided with each batch of thromboplastin made. Extrapolation from human data suggests that an INR of 2 to 3 is as effective as higher values, with less chance for bleeding. Using a warfarin dose of 0.05 to 0.1 mg/kg/day in the dog achieves this INR in about 5 to 7 days. Heparin overlap until the INR is >2 is recommended. When PT is used to monitor warfarin therapy, a goal of 1.25 to 1.5 (to 2) times pretreatment PT at 8 to 10 hours after dosing is advised; the animal is weaned off heparin when the INR is >1.25. The PT is evaluated (several hours after dosing) daily initially, then at progressively increasing time intervals (e.g., twice a week, then once a week, then every month to 2 months) as long as the cat's condition appears stable.

If the PT or INR increases excessively, warfarin is discontinued and vitamin  $K_1$  administered (1 to 2 mg/kg/day administered orally or subcutaneously) until the PT is normal and the packed cell volume (PCV) is stable. Transfu-

sion with fresh frozen plasma, packed red blood cells, or whole fresh blood is sometimes necessary.

# SYSTEMIC ARTERIAL THROMBOEMBOLISM IN DOGS

Arterial TE disease in dogs is relatively uncommon compared with cats. Nevertheless, it has been associated with many conditions, including protein-losing nephropathies, hyperadrenocorticism, neoplasia, chronic interstitial nephritis, HWD, hypothyroidism, gastric dilatation-volvulus, pancreatitis, and several cardiovascular diseases. Kidney disease was present in about half of the dogs with TE disease in one report (Van Winkle, 1993). Vegetative endocarditis is the most common cardiac disease associated with systemic thromboembolism. Other cardiovascular conditions that have been associated with canine TE disease include patent ductus arteriosus (surgical ligation site), dilated cardiomyopathy, myocardial infarction, arteritis, aortic intimal fibrosis, atherosclerosis, aortic dissection, granulomatous inflammatory erosion into the left atrium, and other thrombi in the left heart. TE disease is a rare complication of arteriovenous (A-V) fistulae; it may relate to venous stasis from distal venous hypertension. Aortic TE has occurred in Greyhounds without overt underlying abnormalities as well as in those with protein-losing nephropathy or intramuscular hemangiosarcoma in the thigh muscles. Affected dogs typically present for intermittent rear limb lameness (claudication) and have weak femoral pulses on the affected side, and the thrombi are obvious during abdominal ultrasonography.

Atherosclerosis is uncommon in dogs, but it has been associated with TE disease in this species, as it has in people. Endothelial disruption in areas of atherosclerotic plaque, hypercholesterolemia, increased PAJ-1, and possibly other mechanisms may be involved in thrombus formation. Atherosclerosis may develop with profound hypothyroidism, hypercholesterolemia, or hyperlipidemia. The aorta as well as coronary and other medium to large arteries are affected. Myocardial and cerebral infarctions occur in some cases, and there is a high rate of interstitial myocardial fibrosis in affected dogs.

Vasculitis related to infectious, inflammatory, immunemediated, or toxic disease occasionally underlies TE events. Arteritis of immune-mediated pathogenesis is described in some young Beagles and other dogs. Inflammation and necrosis that affect small to medium-sized arteries may be associated with thrombosis.

Coronary artery thromboembolism causes myocardial ischemia and infarction. Infective endocarditis, neoplasia that involves the heart directly or by neoplastic emboli, coronary atherosclerosis, dilated cardiomyopathy, degenerative mitral valve disease with CHF, and coronary vasculitis are reported causes. In other dogs coronary TE events have occurred with severe renal disease, IMHA, exogenous corticosteroids or hyperadrenocorticism, and acute pancreatic

necrosis. These cases may have TE lesions in other locations as well.

#### **Clinical Features**

There appear to be no age, breed, or sex predilections for arterial TE disease in dogs. As in cats, the distal aorta is the most common location for clinically recognized thromboemboli. In contrast to cats, most dogs have some clinical signs from 1 to 8 weeks before presentation. Less than a quarter of cases have peracute paralysis without prior signs of lameness, as usually occurs in cats. Signs related to the TE event include pain, hindlimb paresis, lameness or weakness (which may be progressive or intermittent), and chewing or hypersensitivity of the affected limb(s) or lumbar area. Although about half of affected dogs present with sudden paralysis, this is often preceded by a variable period of lameness. Intermittent claudication, common in people with peripheral occlusive vascular disease, may be a manifestation of distal aortic TE disease. This involves pain, weakness, and lameness that develop during exercise. These signs intensify until walking becomes impossible, then disappear with rest. Inadequate perfusion during exercise leads to lactic acid accumulation and cramping.

Physical examination findings in dogs with aortic thromboembolism are similar to those in cats, including absent or weak femoral pulses, cool extremities, hindlimb pain, loss of sensation in the digits, hyperesthesia, cyanotic nailbeds, and neuromuscular dysfunction. Occasionally, a brachial or other artery is embolized. TE disease involving an abdominal organ causes abdominal pain, with clinical and laboratory evidence of damage to the affected organ.

Coronary artery thromboembolism is likely to be associated with arrhythmias, as well as ST segment and T wave changes on ECG. Ventricular (or other) tachyarrhythmias are common, but if the atrioventricular (AV) nodal area is injured, conduction block may result. Clinical signs of acute myocardial infarction/necrosis may mimic those of pulmonary TE disease; these include weakness, dyspnea, and collapse. Respiratory difficulty may develop as a result of pulmonary abnormalities or left heart failure (pulmonary edema) depending on the underlying disease and degree of myocardial dysfunction. Some animals with respiratory distress have no radiographically evident pulmonary infiltrates. Increased pulmonary venous pressure preceding overt edema (from acute myocardial dysfunction) or concurrent pulmonary emboli are potential causes. Other findings in animals with myocardial necrosis include sudden death, tachycardia, weak pulses, increased lung sounds or crackles, cough, cardiac murmur, hyperthermia or sometimes hypothermia, and (less commonly) GI signs. Signs of other systemic disease may be concurrent. Acute ischemic myocardial injury that causes sudden death may not be detectable on routine histopathology.

## Diagnosis

Thoracic radiography is used to screen for cardiac abnormalities, especially in animals with systemic arterial TE

disease and for pulmonary changes in animals suspected to have pulmonary thromboemboli. Evidence for CHF or other pulmonary disease associated with TE disease (e.g., neoplasia, HWD, other infections) may also be found.

A complete echocardiographic exam is important to define whether (and what type of) heart disease might be present. Thrombi within the left or right heart chambers and proximal great vessels can be readily seen with two-dimensional echocardiography. In dogs with coronary TE disease, the echocardiographic examination may indicate reduced myocardial contractility with or without regional dysfunction. Areas of myocardial fibrosis secondary to chronic ischemia or infarction appear hyperechoic compared with the surrounding myocardium. Thromboemboli in the distal aorta (or other vessel) may be visible by ultrasonography as well. Doppler studies can demonstrate partial or complete obstruction to blood flow in some cases.

Angiography may be used to document vascular occlusion when ultrasonography is inconclusive or unavailable. It also can show the extent of collateral circulation. The choice of selective or nonselective technique depends on patient size and the suspected location of the clot.

Routine laboratory test results depend largely on the disease process underlying the TE event(s). Systemic arterial TE disease also produces elevated muscle enzyme concentrations from skeletal muscle ischemia and necrosis. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) activities rise soon after the TE event. Widespread muscle injury causes increased lactate dehydrogenase and creatine kinase (CK) activities as well.

Coagulation test results in patients with TE disease are variable. The concentration of FDPs or p-dimer may be increased, but this can occur in patients with inflammatory disease and is not specific for a TE event or DIC. Modestly increased p-dimer concentrations occur in diseases such as neoplasia, liver disease, and IMHA. This could reflect subclinical TE disease or another clot activation mechanism because these conditions are associated with a procoagulant state. Body cavity hemorrhage also causes a rise in D-dimer concentrations. Because this condition is associated with increased fibrin formation, elevated p-dimer levels may not indicate TE disease in such cases. The specificity of p-dimer testing for pathologic thromboembolism is lower at lower p-dimer concentrations, but the high sensitivity at lower concentrations provides an important screening tool. Ddimer testing appears to be as specific for DIC as FDP measurement. A number of assays have been developed to measure p-dimer concentrations in dogs; some are qualitative or semiquantitative (i.e., latex agglutination, immunochromatographic, and immunofiltration tests), others are more quantitative (i.e., immunoturbidity, enzymatic immunoassays). It is important to interpret p-dimer results in the context of other clinical and test findings. Assays for circulating AT and proteins C and S are also available for dogs and cats. Deficiencies of these proteins are associated with increased risk of thrombosis.

Thromboelastography (TEG) provides an easy point-ofcare method of assessing global hemostasis and is quite valuable when evaluating patients with TE disease.

# **Treatment and Prognosis**

The goals of therapy are the same as for cats with TE disease: Stabilize the patient by supportive treatment as indicated, prevent extension of the existing thrombus and additional TE events, and reduce the size of the thromboembolus and restore perfusion. Supportive care is given to improve and maintain adequate tissue perfusion, minimize further endothelial damage and blood stasis, and optimize organ function as well as to allow time for collateral circulation development. Correcting or managing underlying disease(s), to the extent possible, is also important. Antiplatelet and anticoagulant therapies are used to reduce platelet aggregation and growth of existing thrombi as in cats (see p. 199). The results of the TEG, if available, should be used to monitor response to anticoagulants in patients with TE disease.

Management strategies used for TE disease are outlined in Box 12-3. Although fibrinolytic therapy is used in some cases, dosage uncertainties, the need for intensive care, and the potential for serious complications limit its use. The reported streptokinase protocol for dogs is 90,000 IU infused intravenously over 20 to 30 minutes, then continued at a rate of 45,000 IU/hour for 3 (to 12) hours. In dogs, rt-PA has been used as 1 mg/kg boluses administered intravenously q1h for 10 doses, with IV fluid, other supportive therapy, and close monitoring. The half-life of t-PA is about 2 to 3 minutes in dogs, but effects persist longer because of binding to fibrin. The consequences of reperfusion injury present serious complications to thrombolytic therapy. The iron chelator deferoxamine mesylate has been used in an attempt to reduce oxidative damage caused by free radicals involving iron. Allopurinol also has been used but with uncertain results. Clot removal using an embolectomy catheter has not been very effective in cats but might be more successful in dogs of larger size.

Fluid therapy is used to expand vascular volume, support blood pressure, and correct electrolyte and acid/base abnormalities depending on individual patient needs. However, for animals with heart disease and especially CHF, fluid therapy is given only with great caution (if at all). Hypothermia that persists after circulating volume is restored can be addressed with external warming. Specific treatment for heart disease, CHF, and arrhythmias is provided as indicated (see Chapters 3 and 4 and other relevant chapters). Acute respiratory signs may signal CHF, pain, or pulmonary thromboembolism. Differentiation is important because diuretic or vasodilator therapy could worsen perfusion in animals without CHF.

Because acute arterial embolization is particularly painful, analysesic therapy is important in such cases, especially for the first 24 to 36 hours (see Box 12-3). Loosely bandaging the affected limb(s) to prevent self-mutilation may be needed in some animals with aortic TE disease. Renal function and

serum electrolyte concentrations are monitored daily or more frequently if fibrinolytic therapy is used. Continuous ECG monitoring during the first several days can help the clinician detect acute hyperkalemia associated with reperfusion (see Chapter 2, p. 31). In general, the prognosis is poor.

# PROPHYLAXIS AGAINST ARTERIAL THROMBOEMBOLISM

Prophylactic strategies are the same as for cats. Aspirin, LMWH, warfarin, or possibly clopidogrel are agents to consider. If warfarin is used, the usual initial warfarin dose is 0.25 to 0.5 mg (total dose) administered orally q24(to 48)h in cats; 0.1 to 0.2 mg/kg administered orally q24h in dogs. A loading dose of ~0.2 mg/kg for 2 days appears to be safe in dogs.

#### **VENOUS THROMBOSIS**

Thrombosis in large veins is more likely to be clinically evident than thrombosis in small vessels. Cranial vena caval thrombosis has been associated with IMHA and/or immunemediated thrombocytopenia, sepsis, neoplasia, proteinlosing nephropathies, mycotic disease, heart disease, and glucocorticoid therapy (especially in patients with systemic inflammatory disease) in dogs. Most cases have more than one predisposing factor. An indwelling jugular catheter increases the risk for cranial caval thrombosis, probably by causing vascular endothelial damage or laminar flow disruption or by acting as a nidus for clot formation.

Portal vein thrombosis, along with DIC, has occurred in dogs with pancreatitis and pancreatic necrosis. Peritonitis, neoplasia, hepatitis, protein-losing nephropathy, IMHA, and vasculitis have also been diagnosed occasionally in dogs with portal thrombosis. A high proportion of dogs with incidental portal or splenic vein thrombosis are receiving corticosteroids.

Systemic venous thrombosis produces signs related to increased venous pressure upstream from the obstruction. Thrombosis of the cranial vena cava can lead to the cranial caval syndrome. The cranial caval syndrome is characterized by bilaterally symmetric subcutaneous edema of the head, neck, and forelimbs; another cause of this syndrome is external compression of the cranial cava, usually by a neoplastic mass. Pleural effusion occurs commonly. This effusion is often chylous because lymph flow from the thoracic duct into the cranial vena cava is also impaired. Palpable thrombosis extends into the jugular veins in some cases. Because vena caval obstruction reduces pulmonary blood flow and left heart filling, signs of poor cardiac output are common.

Vena caval thrombosis may be visible on ultrasound exam, especially when the clot extends into the right atrium. Portal vein thrombosis and thromboemboli in the aorta or other large peripheral vessels can also be documented on ultrasound examination.

Clinicopathic findings generally reflect underlying disease as well as tissue damage resulting from vascular obstruction.

Cranial caval thrombosis has been associated with thrombocytopenia.

# CHAPTER

# Clinical Manifestations of Nasal Disease

# CHAPTER OUTLINE

GENERAL CONSIDERATIONS NASAL DISCHARGE SNEEZING

Reverse Sneezing STERTOR FACIAL DEFORMITY

#### GENERAL CONSIDERATIONS

The nasal cavity and paranasal sinuses have a complex anatomy and are lined by mucosa. Their rostral portion is inhabited by bacteria in health. Nasal disorders are frequently associated with mucosal edema, inflammation, and secondary bacterial infection. They are often focal or multifocal in distribution. These factors combine to make the accurate diagnosis of nasal disease a challenge that can be met only through a thorough, systematic approach.

Diseases of the nasal cavity and paranasal sinuses typically cause nasal discharge; sneezing; stertor (i.e., snoring or snorting sounds); facial deformity; systemic signs of illness (e.g., lethargy, inappetence, weight loss); or, in rare instances, central nervous system signs. The most common clinical manifestation is nasal discharge. The general diagnostic approach to animals with nasal disease is included in the discussion of nasal discharge. Specific considerations related to sneezing, stertor, and facial deformity follow. Stenotic nares are discussed in the section on brachycephalic airway syndrome (Chapter 18).

# NASAL DISCHARGE

# Classification and Etiology

Nasal discharge is most commonly associated with disease localized within the nasal cavity and paranasal sinuses,

although it may also develop with disorders of the lower respiratory tract, such as bacterial pneumonia and infectious tracheobronchitis, or systemic disorders, such as coagulopathies and systemic hypertension. Nasal discharge is characterized as serous, mucopurulent with or without hemorrhage, or purely hemorrhagic (epistaxis). Serous nasal discharge has a clear, watery consistency. Depending on the quantity and duration of the discharge, a serous discharge may be normal, may be indicative of viral upper respiratory infection, or may precede the development of a mucopurulent discharge. As such, many of the causes of mucopurulent discharge can initially cause serous discharge (Box 13-1).

Mucopurulent nasal discharge is typically characterized by a thick, ropey consistency and has a white, yellow, or green tint. A mucopurulent nasal discharge implies inflammation. Most intranasal diseases result in inflammation and secondary bacterial infection, making this sign a common presentation for most nasal diseases. Potential etiologies include infectious agents, foreign bodies, neoplasia, polyps, and extension of disease from the oral cavity (see Box 13-1). If mucopurulent discharge is present in conjunction with signs of lower respiratory tract disease, such as cough, respiratory distress, or auscultable crackles, the diagnostic emphasis is initially on evaluation of the lower airways and pulmonary parenchyma. Hemorrhage may be associated with mucopurulent exudate from any etiology, but significant and prolonged bleeding in association with mucopurulent discharge is usually associated with neoplasia or mycotic infections.

Persistent pure hemorrhage (epistaxis) can result from trauma, local aggressive disease processes (e.g., neoplasia, mycotic infections), systemic hypertension, or systemic bleeding disorders. Systemic hemostatic disorders that can cause epistaxis include thrombocytopenia, thrombocytopathies, von Willebrand's disease, rodenticide toxicity, and vasculitides. Ehrlichiosis and Rocky Mountain spotted fever can cause epistaxis through several of these mechanisms. Nasal foreign bodies may cause hemorrhage after entry into

Differential Diagnoses for Nasal Discharge in Dogs and Cats

the nasal cavity, but the bleeding tends to subside quickly. Bleeding can also occur after aggressive sneezing from any cause.

# Diagnostic Approach

A complete history and physical examination can be used to prioritize the differential diagnoses for each type of nasal discharge (see Box 13-1). Acute and chronic diseases are defined by obtaining historical information regarding the onset of signs and evaluating the overall condition of the animal. Acute processes, such as foreign bodies or acute feline viral infections, often result in a sudden onset of signs, including sneezing, and the animal's body condition is excellent. In chronic processes, such as mycotic infections or neoplasia, signs are present over a long period of time and the overall body condition can be deleteriously affected. A history of gagging or retching may indicate masses, foreign bodies, or exudate in the caudal nasopharynx.

Nasal discharge is characterized as unilateral or bilateral on the basis of both historical and physical examination findings. When nasal discharge is apparently unilateral, a cold microscope slide may be held close to the external nares to determine the patency of the side of the nasal cavity without discharge. Condensation will not be visible in front of the naris if airflow is obstructed, which suggests that the disease is actually bilateral. Although any bilateral process can cause signs from one side only and unilateral disease can progress to involve the opposite side, some generalizations can be made. Systemic disorders and infectious diseases tend to involve both sides of the nasal cavity, whereas foreign bodies, polyps, and tooth root abscessation tend to cause unilateral discharge. Neoplasia may initially cause unilateral discharge that later becomes bilateral after destruction of the nasal septum.

Ulceration of the nasal plane is highly suggestive of a diagnosis of nasal aspergillosis (Fig. 13-1). Polypoid masses protruding from the external nares in the dog are typical of rhinosporidiosis, and in the cat they are typical of cryptococcosis.

A thorough assessment of the head, including facial symmetry, teeth, gingiva, hard and soft palate, mandibular lymph nodes, and eyes, should be performed. Mass lesions invading beyond the nasal cavity can cause deformity of facial bones or the hard palate, exophthalmos, or inability to retropulse the eye. Pain on palpation of the nasal bones is suggestive of aspergillosis. Gingivitis, dental calculi, loose teeth, or pus in the gingival sulcus should raise an index of suspicion for oronasal fistulae or tooth root abscess, especially if unilateral nasal discharge is present. Foci of inflammation and folds of hyperplastic gingiva in the dorsum of the mouth should be probed for oronasal fistulae. A normal examination of the oral cavity does not rule out oronasal fistulae or tooth root abscess. The hard and soft palates are examined for deformation, erosions, or congenital defects such as clefts or hypoplasia. Mandibular lymph node enlargement suggests active inflammation or neoplasia, and fine-needle aspirates of enlarged or firm nodes are evaluated for organisms, such as

PIG 13-1
Depigmentation and ulceration of the planum nasale is suggestive of nasal aspergillosis. The visible lesions usually extend from one or both nares and are most severe ventrally. This dog has unilateral depigmentation and mild ulceration.

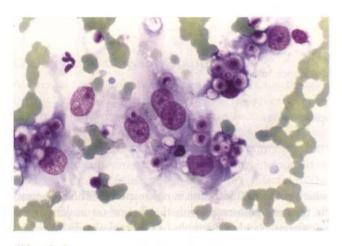

FIG 13-2

Photomicrograph of fine-needle aspirate of a cat with facial deformity. Identification of cryptococcal organisms provides a definitive diagnosis for cats with nasal discharge or facial deformity. Organisms can often be found in swabs of nasal discharge, fine-needle aspirates of facial masses, or fine-needle aspirates of enlarged mandibular lymph nodes. The organisms are variably sized, ranging from about 3 to 30  $\mu$ m in diameter, with a wide capsule and narrow-based budding. They may be found intracellularly or extracellularly.

Cryptococcus, and neoplastic cells (Fig. 13-2). A fundic examination should always be performed because active chorioretinitis can occur with cryptococcosis, ehrlichiosis, and malignant lymphoma (Fig. 13-3). Retinal detachment can occur with systemic hypertension or mass lesions extending into the bony orbit. With epistaxis, identification of petechiae or hemorrhage in other mucous membranes, skin, ocular fundus, feces, or urine supports a systemic bleeding disorder. Note that melena may be present as a result of swallowing blood from the nasal cavity.

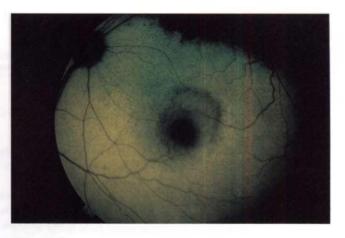

FIG 13-3
Fundic examination can provide useful information in animals with signs of respiratory tract disease. This fundus from a cat with chorioretinitis caused by cryptococcosis has a large, focal, hyporeflective lesion in the area centralis. Smaller regions of hyporeflectivity were also seen. The optic disk is in the upper left-hand corner of the photograph. (Courtesy M. Davidson, North Carolina State University,

Raleigh, N.C.)

Diagnostic tests that should be considered for a dog or cat with nasal discharge are included in Box 13-2. The signalment, history, and physical examination findings dictate in part which diagnostic tests are ultimately required to establish the diagnosis. As a general rule, less invasive diagnostic tests are performed initially. A complete blood count (CBC) with platelet count, coagulation panel (i.e., activated clotting time or prothrombin and partial thromboplastin times), buccal mucosal bleeding time, and arterial blood pressure should be evaluated in dogs and cats with epistaxis. Von Willebrand's factor assays are performed in purebred dogs with epistaxis and in dogs with prolonged mucosal bleeding times. Determination of Ehrlichia spp. and Rocky Mountain spotted fever titers are indicated for dogs with epistaxis in regions of the country where potential exposure to these rickettsial agents exists. Testing for Bartonella sp. is also considered. Testing for feline immunodeficiency virus (FIV) and feline leukemia virus (FeLV) should be performed in cats with chronic nasal discharge and potential exposure. Cats infected with FeLV may be predisposed to chronic infection with herpesvirus or calicivirus, whereas those with FIV may have chronic nasal discharge without concurrent infection with these upper respiratory viruses.

Most animals with intranasal disease have normal thoracic radiographs. However, thoracic radiographs may be useful in identifying primary bronchopulmonary disease, pulmonary involvement with cryptococcosis, and rare metastases from neoplastic disease. They may also be a useful preanesthetic screening test for animals that will require nasal imaging, rhinoscopy, and nasal biopsy.

Cytologic evaluation of superficial nasal swabs may identify cryptococcal organisms in cats (see Fig. 13-2). Nonspecific findings include proteinaceous background, moderate

to severe inflammation, and bacteria. Tests to identify herpesvirus and calicivirus infections may be performed in cats with acute and chronic rhinitis. These tests are most useful in evaluating cattery problems rather than the condition of an individual cat (see Chapter 15).

Fungal titer determinations are available for aspergillosis in dogs and cryptococcosis in dogs and cats. The test for aspergillosis detects antibodies in the blood. A single positive test result strongly suggests active infection by the organism; however, a negative titer does not rule out the disease. In either case, the result of the test must be interpreted in conjunction with results of nasal imaging, rhinoscopy, and nasal histology and culture.

The blood test of choice for cryptococcosis is the latex agglutination capsular antigen test (LCAT). Because organism identification is usually possible in specimens from infected organs, organism identification is the method of choice for a definitive diagnosis. The LCAT is performed if cryptococcosis is suspected but an extensive search for the organism has failed. The LCAT is also performed in animals with a confirmed diagnosis as a means of monitoring therapeutic response (see Chapter 98).

In general, nasal radiography or computerized tomography (CT), rhinoscopy, and biopsy are required to establish a diagnosis of intranasal disease in most dogs and in cats in

which acute viral infection is not suspected. These diagnostic tests are performed with the dog or cat under general anesthesia. Nasal radiographs or CT scans are obtained first, followed by oral examination and rhinoscopy and then specimen collection. This order is recommended because the results of radiography or CT and rhinoscopy are often useful in the selection of biopsy sites. In addition, hemorrhage from biopsy sites could obscure or alter radiographic and rhinoscopic detail if the specimen were collected first. In dogs and cats suspected of having acute foreign body inhalation, rhinoscopy is performed first in the hopes of identifying and removing the foreign material. (See Chapter 14 for more detail on nasal radiography, CT, and rhinoscopy.)

The combination of radiography, rhinoscopy, and nasal biopsy has a diagnostic success rate of approximately 80% in dogs. Dogs with persistent signs in which a diagnosis cannot be obtained following the assessment described earlier require further evaluation. It is more difficult to evaluate the success rate for cats. High proportions of cats with chronic nasal discharge suffer from feline chronic rhinosinusitis (idiopathic rhinitis) and are diagnosed only through exclusion. Cats are evaluated further only if signs suggestive of another disease are found during any part of their evaluation or if the clinical signs are progressive or intolerable to the owners.

Nasal CT is considered if not performed previously and if a diagnosis has not been made. CT provides excellent visualization of all of the nasal turbinates and may allow the identification of small masses that are not visible on nasal radiography or rhinoscopy. CT is also more accurate than nasal radiography in determining the extent of nasal tumors. Magnetic resonance imaging (MRI) may be more accurate than CT in the assessment of soft tissues, such as nasal neoplasia. In the absence of a diagnosis, nasal imaging (preferably CT or MRI), rhinoscopy, and biopsy can be repeated after a 1- to 2-month delay.

Exploratory rhinotomy with turbinectomy is the final diagnostic test. Surgical exploration of the nose allows direct visualization of the nasal cavity for the presence of foreign bodies, mass lesions, or fungal mats and for obtaining biopsies and culture specimens. The potential benefits of surgery, however, should be weighed against the potential complications associated with rhinotomy and turbinectomy. The Suggested Readings section offers surgical references.

#### **SNEEZING**

# **Etiology and Diagnostic Approach**

A sneeze is an explosive release of air from the lungs through the nasal cavity and mouth. It is a protective reflex to expel irritants from the nasal cavity. Intermittent, occasional sneezing is considered normal. Persistent, paroxysmal sneezing should be considered abnormal. Disorders commonly associated with acute-onset, persistent sneezing include nasal foreign body and feline upper respiratory infection. The canine nasal mite, *Pneumonyssoides caninum*, and exposure to irritating aerosols are less common causes of sneezing. All the nasal diseases considered as differential diagnoses for nasal discharge are also potential causes for sneezing; however, animals with these diseases generally present with nasal discharge as the primary complaint.

The owners should be questioned carefully concerning the possible recent exposure of the pet to foreign bodies (e.g., rooting in the ground, running through grassy fields), powders, and aerosols or, in cats, exposure to new cats or kittens. Sneezing is an acute phenomenon that often subsides with time. A foreign body should not be excluded from the differential diagnoses just because the sneezing subsides. In the dog a history of acute sneezing followed by the development of a nasal discharge is suggestive of a foreign body.

Other findings may help narrow the list of differential diagnoses. Dogs with foreign bodies may paw at their nose. Foreign bodies are typically associated with unilateral, mucopurulent nasal discharge, although serous or serosanguineous discharge may be present initially. Foreign bodies in the caudal nasopharynx may cause gagging, retching, or reverse sneezing. The nasal discharge associated with reactions to aerosols, powders, or other inhaled irritants is usually bilateral and serous in nature. In cats other clinical signs supportive of a diagnosis of upper respiratory infection, such as

conjunctivitis and fever, may be present as well as a history of exposure to other cats or kittens.

Dogs in which acute, paroxysmal sneezing develops should undergo prompt rhinoscopic examination (see Chapter 14). With time, foreign material may become covered with mucus or migrate deeper into the nasal passages, and any delay in performing rhinoscopy may interfere with the identification and removal of the foreign bodies. Nasal mites are also identified rhinoscopically. In contrast, cats sneeze more often as a result of acute viral infection rather than a foreign body. Immediate rhinoscopic examination is not indicated unless there has been known exposure to a foreign body or the history and physical examination findings do not support a diagnosis of viral upper respiratory infection.

#### REVERSE SNEEZING

Reverse sneezing is a paroxysm of noisy, labored inspiration initiated by nasopharyngeal irritation. Such irritation can be the result of a foreign body located dorsal to the soft palate or nasopharyngeal inflammation. Foreign bodies usually originate from grass or plant material that is prehended into the oral cavity and which, presumably, is coughed up or migrates into the nasopharyx. Epiglottic entrapment of the soft palate has also been proposed as a cause. The majority of cases are idiopathic. Small-breed dogs are usually affected, and signs may be associated with excitement or drinking. The paroxysms last only a few seconds and do not significantly interfere with respiration. Although these animals usually display this sign throughout their life, the problem rarely progresses.

The diagnosis is generally made by a thorough history and physical examination. Generally, no treatment is needed because the episodes are self-limiting. Some owners report that massaging the neck shortens an ongoing episode or that administration of antihistamines decreases the frequency and severity of episodes, but controlled studies are lacking. Further evaluation for potential nasal or pharyngeal disorders is indicated if syncope, exercise intolerance, or other signs of respiratory disease are reported or if the reverse sneezing is severe or progressive.

#### **STERTOR**

Stertor refers to coarse, audible snoring or snorting sounds associated with breathing. It indicates upper airway obstruction. Stertor is most often the result of pharyngeal disease (see Chapter 16). Intranasal causes of stertor include obstruction caused by congenital deformities, masses, exudate, or blood clots. Evaluation for nasal disease proceeds as described for nasal discharge.

# **FACIAL DEFORMITY**

Carnaissal tooth root abscess in dogs can result in swelling, often with drainage, adjacent to the nasal cavity and beneath

Facial deformity characterized by firm swelling over the maxilla in two cats. **A**, Deformity in this cat was the result of carcinoma. Notice the ipsilateral blepharospasm. **B**, Deformity in this cat was the result of cryptococcosis. A photomicrograph of the fine-needle aspirate of this swelling is provided in Fig. 13-2.

the eye. Excluding dental disease, the most common causes of facial deformity adjacent to the nasal cavity are neoplasia and, in cats, cryptococcosis (Fig. 13-4). Visible swellings can often be evaluated directly through fine-needle aspiration or punch biopsy (see Fig. 13-2). Further evaluation proceeds as for nasal discharge if such an approach is not possible or is unsuccessful.

## NASAL IMAGING

Nasal imaging is a key component of the diagnostic assessment of animals with signs of intranasal disease, allowing assessment of bone and soft tissue structures that are not visible by physical examination or rhinoscopy. Nasal radiography is the type of imaging most readily available and is described in some detail. However, computed tomography (CT) provides images that are superior to radiographs in the majority of cases. The role of magnetic resonance imaging (MRI) in the evaluation of canine and feline nasal disease has not been well established, but it likely provides more accurate images of soft tissue than does CT. MRI is not used routinely on account of its limited availability and relatively high expense.

Because nasal imaging rarely provides a definitive diagnosis, it is usually followed by rhinoscopy and nasal biopsy. All of these procedures require general anesthesia. Imaging should be performed before, rather than after, these procedures for two reasons: (1) The results of nasal imaging help the clinician direct biopsy instruments to the most abnormal regions, and (2) rhinoscopy and biopsy cause hemorrhage, which obscures soft tissue detail.

#### RADIOGRAPHY

Nasal radiographs are useful for identifying the extent and severity of disease, localizing sites for biopsy within the nasal cavity, and prioritizing the differential diagnoses. The dog or cat must be anesthetized to prevent motion and facilitate positioning. Radiographic abnormalities are often subtle. At least four views should be taken: lateral, ventrodorsal, intraoral, and frontal sinus or skyline. Radiographs of the tympanic bullae are obtained in cats because of the frequent occurrence of otitis media in cats with nasal disease (Detweiler et al., 2006). Determination of involvement of the middle ear is particularly important in cats with suspected nasopharyngeal polyps. Lateral-oblique views or dental films are also indicated in dogs and cats with possible tooth root abscess. The intraoral view is particularly helpful for detecting subtle asymmetry between the left and right nasal cavities.

The intraoral view is taken with the animal in sternal recumbency. The corner of a nonscreen film is placed above the tongue as far into the oral cavity as possible, and the radiographic beam is positioned directly above the nasal cavity (Figs. 14-1 and 14-2). The frontal sinus view is obtained with the animal in dorsal recumbency. Adhesive tape can be used to support the body and draw the forelimbs caudally, out of the field. The head is positioned perpendicular to the spine and the table by drawing the muzzle toward the sternum with adhesive tape. Endotracheal tube and anesthetic tubes are displaced lateral to the head to remove them from the field. A radiographic beam is positioned directly above the nasal cavity and frontal sinuses (Figs. 14-3 and 14-4). The frontal sinus view identifies disease involving the frontal sinuses, which in diseases such as aspergillosis or neoplasia may be the only area of disease involvement. The tympanic bullae are best seen with an open-mouth projection in which the beam is aimed at the base of the skull (Figs. 14-5 and 14-6). The bullae are also evaluated individually by lateral-oblique films, offsetting each bulla from the surrounding skull.

Nasal radiographs are evaluated for increased fluid density, loss of turbinates, lysis of facial bones, radiolucency at the tips of the tooth roots, and the presence of radiodense

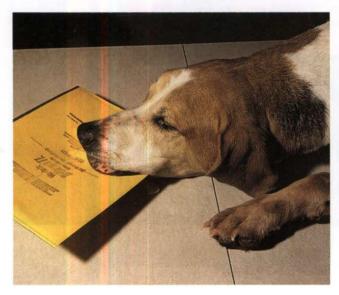

FIG 14-1
Positioning of a dog for intraoral radiographs.

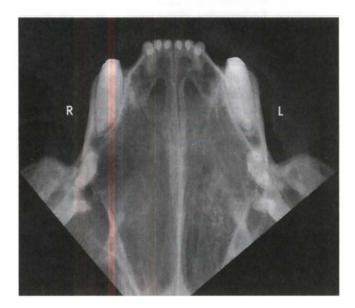

FIG 14-2
Intraoral radiograph of a cat with carcinoma. Normal fine turbinate pattern is visible on the left side (L) of nasal cavity and provides basis for comparison with the right side (R). Turbinate pattern is less apparent on right side, and an area of turbinate lysis can be seen adjacent to the first premolar.

foreign bodies (Box 14-1). Increased fluid density can be caused by mucus, exudate, blood, or soft tissue masses such as polyps, tumors, or granulomas. Soft tissue masses may appear localized, but the surrounding fluid often obscures their borders. A thin rim of lysis surrounding a focal density may represent a foreign body. Fluid density within the frontal sinuses may represent normal mucus accumulation caused by obstruction of drainage into the nasal cavity, extension of disease into the frontal sinuses from the nasal cavity, or primary disease involving the frontal sinuses.

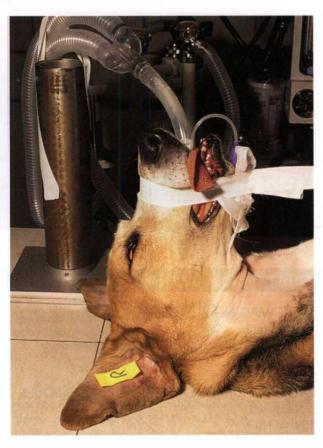

FIG 14-3
Positioning of a dog for frontal sinus radiographs. The endotracheal and anesthetic tubes are displaced laterally in this instance by taping them to an upright metal cylinder.

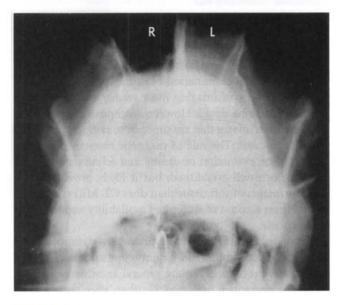

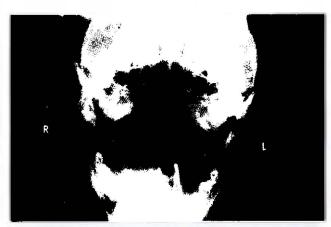

FIG 14-4
Frontal sinus view of a dog with a nasal tumor. The left frontal sinus (L) has increased soft tissue density compared with the air-filled sinus on the right side (R).

Positioning of a cat for open-mouth projection of the tympanic bullae. Beam (arrow) is aimed through the mouth toward the base of the skull. Adhesive tape (t) is holding head and mandible in position.

**FIG 14-6**Radiograph obtained from a cat with nasopharyngeal polypusing the open-mouth projection demonstrated in Fig. 14-5. The left bulla has thickening of bone and increased fluid density, indicating bulla osteitis and probable extension of the polyp.

FIG 14-7
Intraoral radiograph of a dog with nasal aspergillosis. Focal areas of marked turbinate lysis are present on both sides of the nasal cavity. The vomer bone remains intact.

Loss of the normal fine turbinate pattern in combination with increased fluid density within the nasal cavity can occur with chronic inflammatory conditions of any etiology. Early neoplastic changes can also be associated with an increase in soft tissue density and destruction of the turbinates (see Figs. 14-2 and 14-4). More aggressive neoplastic changes may include marked lysis or deformation of the vomer and/or facial bones. Multiple, well-defined lytic zones within the nasal cavity and increased radiolucency in the rostral portion of the nasal cavity suggest aspergillosis (Fig. 14-7). The vomer bone may be roughened but is rarely destroyed. Previous traumatic fracture of the nasal bones and secondary osteomyelitis can also be detected radiographically.

# COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT provides excellent visualization of the nasal turbinates, nasal septum, hard palate, and cribriform plate (Fig. 14-8). In cats CT is also useful for determining middle ear involvement with nasopharyngeal polyps or other nasal disease. CT is more accurate than conventional radiography in assessing the extent of neoplastic disease insofar as it allows more

BOX 14-1

Radiographic Signs of Common Nasal Diseases\*

#### Feline Chronic Rhinosinusitis

Soft tissue opacity within nasal cavity, possibly asymmetric Mild turbinate lysis

Soft tissue opacity in frontal sinus(es)

#### Nasopharyngeal Polyp

Soft tissue opacity above soft palate Soft tissue opacity within nasal cavity, usually unilateral Mild turbinate lysis possible

Bulla osteitis: soft tissue opacity within bulla, thickening of

#### Nasal Neoplasia

Soft tissue opacity, possibly asymmetric Turbinate destruction Vomer bone and/or facial bone destruction Soft tissue mass external to facial bones

#### **Nasal Aspergillosis**

Well-defined lucent areas within the nasal cavity Increased radiolucency rostrally Increased soft tissue opacity possibly also present No destruction of vomer or facial bones, although signs often Vomer bone sometimes roughened

Fluid density within the frontal sinus; frontal bones sometimes thickened or moth-eaten

#### Cryptococcosis

Soft tissue opacity, possibly asymmetric Turbinate lysis Facial bone destruction Soft tissue mass external to facial bones

#### Canine Chronic/Lymphoplasmacytic Rhinitis

Soft tissue opacity Lysis of nasal turbinates, especially rostrally

#### **Allergic Rhinitis**

Increased soft tissue opacity Mild turbinate lysis possible

#### Tooth Root Abscesses

Radiolucency adjacent to tooth roots, commonly apically

#### Foreign Bodies

Mineral and metallic dense foreign bodies readily identified Plant foreign bodies: focal, ill-defined, increased soft tissue

Lucent rim around abnormal tissue (rare)

accurate localization of mass lesions for subsequent biopsy than nasal radiography, and it is instrumental for radiotherapy treatment planning. Determination of the integrity of the cribriform plate is important in treatment planning for nasal aspergillosis. CT may also identify the presence of lesions in animals with undiagnosed nasal disease when other techniques have failed. Typical lesions are as described in Box 14-1. MRI may be more accurate than CT in the assessment of soft tissues, such as nasal neoplasia.

#### RHINOSCOPY

Rhinoscopy allows visual assessment of the nasal cavity through the use of a rigid or flexible endoscope or an otoscopic cone. Rhinoscopy is used to visualize and remove foreign bodies; to grossly assess the nasal mucosa for the presence of inflammation, turbinate erosion, mass lesions, fungal plaques, and parasites; and to aid in the collection of nasal specimens for histopathologic examination and culture. Complete rhinoscopy always includes a thorough examination of the oral cavity and caudal nasopharynx, in addition to visualization of the nasal cavity through the external nares.

The extent of visualization depends on the quality of the equipment and the outside diameter of the rhinoscope. A narrow (2- to 3-mm diameter), rigid fiberoptic endoscope provides good visualization through the external nares in most patients. Endoscopes without biopsy or suction channels are preferable because of their small outside diameter. Some of these systems are relatively inexpensive, including one model that can be attached to a standard otoscope handle for the light source (Fig. 14-9). Scopes designed for arthroscopy, cystoscopy, and sexing of birds also work well. In medium to large dogs, a flexible pediatric bronchoscope (e.g., 4-mm outer diameter) can be used. Flexible endoscopes are now available in smaller sizes, similar to small rigid scopes, although they are relatively more expensive and fragile. If an endoscope is not available, the rostral region of the nasal cavity can be examined with an otoscope. Human pediatric otoscopic cones (2- to 3-mm diameter) can be purchased for examining cats and small dogs.

General anesthesia is required for rhinoscopy. Rhinoscopy is usually performed immediately after nasal imaging unless a foreign body is strongly suspected. The oral cavity and caudal nasopharynx should be assessed first. During the oral examination the hard and soft palates are visually examined and palpated for deformation, erosions, or defects, and the gingival sulci are probed for fistulae.

The caudal nasopharynx is evaluated for the presence of nasopharyngeal polyps, neoplasia, and foreign bodies. Foreign bodies, particularly grass or plant material, are commonly found in this location in cats and occasionally in dogs.

<sup>\*</sup> Note that these descriptions represent typical cases and are not specific findings.

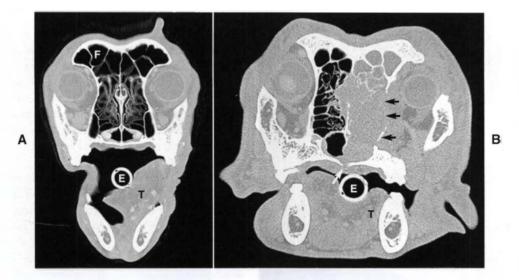

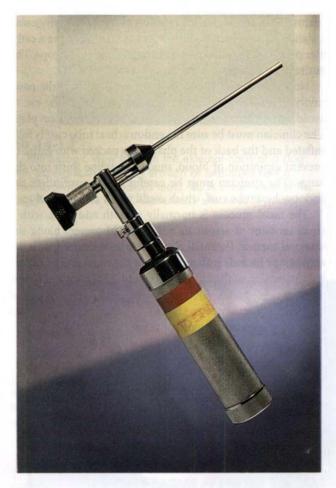

FIG 14-8

CT scans of nasal cavity of two different dogs at the level of the eyes. **A,** Normal nasal turbinates and intact nasal septum are present. **B,** Neoplastic mass is present within the right cavity; it is eroding through the hard palate (white arrow), the frontal bone into the retrobulbar space (small black arrows), and the nasal septum. The tumor also extends into the right frontal sinus. F, Frontal sinus; E, endotracheal tube; T, tongue.

Rigid endoscope (diameter, 3.5 mm; length, 4 inches) suitable for rhinoscopy that uses a standard otoscope handle as a light source. (MDS, Inc., Brandon, Fla.)

FIG 14-10

The caudal nasopharynx is best examined with a flexible endoscope that is passed into the oral cavity and retroflexed 180 degrees around the edge of the soft palate, as shown in this radiograph.

The caudal nasopharynx is best visualized with a flexible endoscope that is passed into the oral cavity and retroflexed around the soft palate (Figs. 14-10 through 14-12). Alternatively, the caudal nasopharynx can be evaluated with the aid of a dental mirror, penlight, and spay hook, which is attached to the caudal edge of the soft palate and pulled forward to improve visualization of the area. It may be possible to visualize nasal mites of infected dogs by observing the caudal nasopharynx while flushing anesthetic gases (e.g., halothane and oxygen) through the nares.

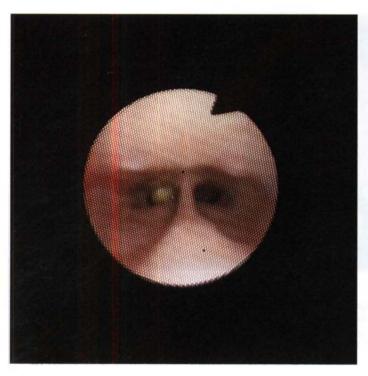

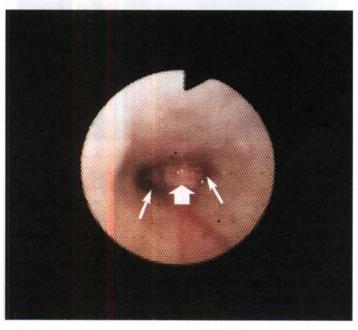

FIG 14-11

View of the internal nares obtained by passing a flexible bronchoscope around the edge of the soft palate in a dog with sneezing. A small white object is seen within the left nasal cavity adjacent to the septum. Note that the septum is narrow and the right internal naris is oval in shape and not obstructed. On removal, the object was found to be a popcorn kernel. The dog had an abnormally short soft palate, and the kernel presumably entered the caudal nasal cavity from the oropharynx.

HG 14-12

View of the internal nares (thin arrows) obtained by passing a flexible bronchoscope around the edge of the soft palate in a dog with nasal discharge. A soft tissue mass (broad arrow) is blocking the normally thin septum and is partially obstructing the airway lumens. Compare this view with the appearance of the normal septum and right internal naris in Fig. 14-11

Rhinoscopy must be performed patiently, gently, and thoroughly to maximize the likelihood of identifying gross abnormalities and minimize the risk of hemorrhage. The more normal side of the nasal cavity is examined first. The tip of the scope is passed through the naris with the tip pointed medially. Each nasal meatus is evaluated, beginning ventrally and working dorsally to ensure visualization should hemorrhage develop during the procedure. Each nasal meatus should be examined as far caudally as the scope can be passed without trauma.

Although the rhinoscope can be used to evaluate the large chambers of the nose, many of the small recesses cannot be examined, even with the smallest endoscopes. Thus disease or a foreign body may be missed if only these small recesses are involved. Swollen and inflamed nasal mucosa, hemorrhage caused by the procedure, and the accumulation of exudate and mucus can also interfere with visualization of the nasal cavity. Foreign bodies and masses are frequently coated and effectively hidden by seemingly insignificant amounts of mucus, exudate, or blood. The tenacious material must be removed using a rubber catheter with the tip cut off attached to a suction unit. If necessary, saline flushes can also be used, although resulting fluid bubbles may further interfere with visualization. Some clinicians prefer to maintain continuous saline infusion of the nasal cavity using a standard intravenous administration set attached to a catheter or, if available, the biopsy channel of the rhinoscope. The entire examination is done "under water."

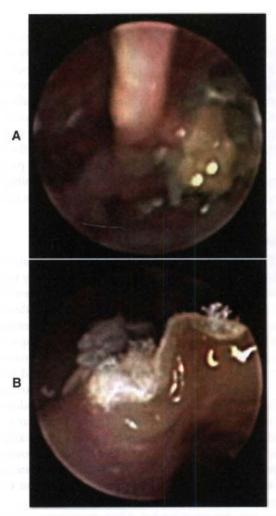

No catheter should ever be passed blindly into the nasal cavity beyond the level of the medial canthus of the eye to avoid entering the cranial vault through the cribriform plate. The clinician must be sure the endotracheal tube cuff is fully inflated and the back of the pharynx is packed with gauze to prevent aspiration of blood, mucus, or saline flush into the lungs. The clinician must be careful not to overinflate the endotracheal tube cuff, which could result in a tracheal tear.

The nasal mucosa is normally smooth and pink, with a small amount of serous to mucoid fluid present along the mucosal surface. Potential abnormalities visualized with the rhinoscope include inflammation of the nasal mucosa; mass lesions; erosion of the turbinates (Fig. 14-13, *A*); mats of fungal hyphae (Fig. 14-13, *B*); foreign bodies; and, rarely, nasal mites or *Capillaria* worms (Fig. 14-14). Differential diagnoses for gross rhinoscopic abnormalities are provided in Box 14-2.

The location of any abnormality should be noted, including the meatus involved (common, ventral, middle, dorsal), the medial-to-lateral orientation within the meatus, and the distance caudal from the naris. Exact localization is critical for directing instruments for the retrieval of foreign bodies or nasal biopsy should visual guidance become impeded by hemorrhage or size of the cavity.

# NASAL BIOPSY: INDICATIONS AND TECHNIQUES

Visualization of a foreign body or nasal parasites during rhinoscopy establishes a diagnosis. For many dogs and cats,

however, the diagnosis must be based on cytologic, histologic, and microbiologic evaluation of nasal biopsy specimens. Nasal biopsy specimens should be obtained immediately after nasal imaging and rhinoscopy while the animal is still anesthetized. These earlier procedures can help localize the lesion, maximizing the likelihood of obtaining material representative of the primary disease process.

Nasal biopsy techniques include nasal swab, nasal flush, pinch biopsy, and turbinectomy. Fine-needle aspirates can be obtained from mass lesions as described in Chapter 75. Pinch biopsy is the preferred nonsurgical method of specimen collection. It is more likely to provide pieces of nasal tissue that extend beneath the superficial inflammation, which is common to many nasal disorders, than nasal swabs or flushes. In addition, the pieces of tissue obtained with this more aggressive method can be evaluated histologically, whereas the material obtained with the less traumatic techniques may be suitable only for cytologic analysis. Histopathologic examination is preferred over cytologic examination in most cases because the marked inflammation that accompanies many nasal diseases makes it difficult to cytologically differentiate primary from secondary inflammation and reactive from neoplastic epithelial cells. Carcinomas can also appear cytologically as lymphoma and vice versa.

Regardless of the technique used (except for nasal swab), the cuff of the endotracheal tube should be inflated (avoiding overinflation) and the caudal pharynx packed with gauze sponges to prevent the aspiration of fluid. Intravenous crystalloid fluids (10 to 20 ml/kg/h plus replacement of estimated blood loss) are recommended during the procedure to counter the hypotensive effects of prolonged anesthesia and blood loss from hemorrhage after biopsy. Blood-clotting capabilities should be assessed before the more aggressive biopsy techniques are performed if there is any history of hemorrhagic exudate or epistaxis or any other indication of coagulopathy.

# **NASAL SWAB**

The least traumatic techniques are the nasal swab and nasal flush. Unlike the other collection techniques, nasal swabs can be collected from an awake animal. Nasal swabs are useful for identifying cryptococcal organisms cytologically and should be collected early in the evaluation of cats with chronic rhinitis. Other findings are generally nonspecific. Exudate immediately within the external nares or draining from the nares is collected using a cotton-tipped swab. Relatively small swabs are available (e.g., Dacron swabs; Puritan Medical Products Co. LLC) that can facilitate specimen collection from cats with minimal discharge. The swab is then rolled on a microscope slide. Routine cytologic stains are generally used, although India ink can be applied to demonstrate cryptococcal organisms (see Chapter 98).

#### **NASAL FLUSH**

Nasal flush is a minimally invasive technique. A soft catheter is positioned in the caudal region of the nasal cavity via the oral cavity and internal nares, with the tip of the catheter pointing rostrally. With the animal in sternal recumbency and the nose pointed toward the floor, approximately 100 ml of sterile saline solution is forcibly injected in pulses by syringe. The fluid exiting the external nares is collected in a bowl and can be examined cytologically. Occasionally nasal mites can be identified in nasal flushings. Magnification or placement of dark paper behind the specimen for contrast may be needed to visualize the mites. A portion of fluid can also be filtered through a gauze sponge. Large particles trapped in the sponge can be retrieved and submitted for histopathologic analysis. These specimens are often insufficient for providing a definitive diagnosis.

#### PINCH BIOPSY

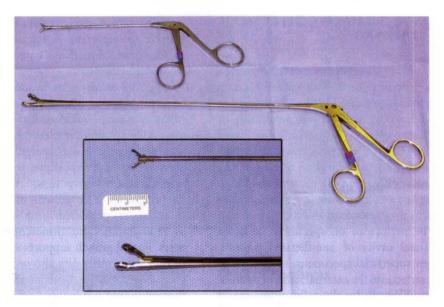

Pinch biopsy is the author's preferred method of nasal biopsy. In the pinch biopsy technique, alligator cup biopsy forceps (minimum size,  $2 \times 3$  mm) are used to obtain pieces of nasal mucosa for histologic evaluation (Fig. 14-15). Full-thickness tissue specimens can be obtained, and guided specimen collection is more easily performed with this technique than with previously described methods. The biopsy forceps are passed adjacent to a rigid endoscope and directed to any gross lesions. If a flexible scope is used, biopsy instruments can be passed through the biopsy channel of the endoscope. The resulting specimens are extremely small and may not be of sufficient quality for diagnostic purposes. Larger alligator forceps are preferred. If lesions are not present grossly but are present radiographically or by CT, the biopsy instrument can be guided using the relationship of the lesion to the upper teeth.

After the first piece is taken, bleeding will prevent further visual guidance; therefore the forceps are passed blindly to the position identified during rhinoscopic examination (e.g., meatus involved and depth from external naris). If a mass is present, the forceps are passed in a closed position until just before the mass is reached. The forceps are then opened and passed a short distance farther until resistance is felt. Larger forceps, such as a mare uterine biopsy instrument, are useful for collecting large volumes of tissue from medium to large size dogs with nasal masses. No forceps should ever be passed into the nasal cavity deeper than the level of the medial canthus of the eye without visual guidance to keep from penetrating the cribriform plate.

A minimum of six tissue specimens (using a  $2 \times 3$  mm forcep or larger) should be obtained from any lesion. If no localizable lesion is identified radiographically or rhinoscopically, multiple biopsies (usually 6 to 10) are obtained randomly from both sides of the nasal cavity.

### **TURBINECTOMY**

Turbinectomy provides the best tissue specimens for histologic examination and allows the clinician to remove abnormal or poorly vascularized tissues, debulk fungal granulomas, and place drains for subsequent topical nasal therapy. Turbinectomy is performed through a rhinotomy incision and is a more invasive technique than those previ-

**FIG 14-15** Cup biopsy forceps are available in different sizes. To obtain sufficient tissue, a minimum size of  $2 \times 3$  mm is recommended. The larger forceps are particularly useful for obtaining biopsies from nasal masses in dogs.

ously described. Turbinectomy is a reasonably difficult surgical procedure that should be considered only when other less invasive techniques have failed to establish the diagnosis. Potential operative and postoperative complications include pain, excessive hemorrhage, inadvertent entry into the cranial vault, and recurrent nasal infections. Cats may be anorectic postoperatively. Placement of an esophagostomy or gastrostomy tube (see Chapter 30) should be considered if necessary to provide a means for meeting nutritional requirements during the recovery period. (See Suggested Readings in Chapter 13 for information on the surgical procedure.)

#### Complications

The major complication associated with nasal biopsy is hemorrhage. The severity of hemorrhage depends on the method used to obtain the biopsy, but even with aggressive techniques the hemorrhage is rarely life threatening. When any technique is used, the floor of the nasal cavity is avoided to prevent damage to major blood vessels. For minor hemorrhage, the rate of administration of intravenous fluids should be increased and manipulations within the nasal cavity should be stopped until the bleeding subsides. Cold saline solution with or without diluted epinephrine (1:100,000) can be gently infused into the nasal cavity. Persistent severe hemorrhage can be controlled by packing the nasal cavity with umbilical tape. The tape must be packed through the nasopharynx as well as through the external nares or the blood will only be redirected. Similarly, placing swabs or gauze in the external nares serves only to redirect blood caudally. In the rare event of uncontrolled hemorrhage, the carotid artery on the involved side can be ligated without subsequent adverse effects. Rhinotomy should not be attempted. In the vast majority of animals, only time or cold saline infusions are required to control hemorrhage. The fear of severe hemorrhage should not prevent the collection of good-quality tissue specimens.

Trauma to the brain is prevented by never passing any object into the nasal cavity beyond the level of the medial canthus of the eye without visual guidance. The distance from the external nares to the medial canthus is noted by holding the instrument or catheter against the face, with the tip at the medial canthus. The level of the nares is marked on the instrument or catheter with a piece of tape or marking pen. The object should never be inserted beyond that mark.

Aspiration of blood, saline solution, or exudate into the lungs must be avoided. A cuffed endotracheal tube should be in place during the procedure, and the caudal pharynx should be packed with gauze after visual assessment of the oral cavity and nasopharynx. The cuff should be sufficiently inflated to prevent audible leakage of air during gentle compression of the reservoir bag of the anesthesia machine. Overinflation of the cuff may lead to tracheal trauma or tear. The nose is pointed toward the floor over the end of the examination table, allowing blood and fluid to drip out from the external nares after rhinoscopy and biopsy. Finally, the caudal pharynx is examined during gauze removal and before extubation for visualization of continued accumulation of fluid. Gauze sponges are counted during placement and then recounted during removal so that none is inadvertently left behind.

# NASAL CULTURES: SAMPLE COLLECTION AND INTERPRETATION

Microbiologic cultures of nasal specimens are recommended but can be difficult to interpret. Aerobic and anaerobic bacterial cultures, mycoplasmal cultures, and fungal cultures can be performed on material obtained by swab, nasal flush, or tissue biopsy. According to Harvey (1984), the normal nasal flora can include *Escherichia coli*, *Staphylococcus*, *Streptococcus*, *Pseudomonas*, *Pasteurella*, and *Aspergillus* organisms and a variety of other aerobic and anaerobic bacteria and fungi. Thus bacterial or fungal growth from nasal specimens does not necessarily confirm the presence of infection.

Cultures should be performed on specimens collected within the caudal nasal cavity of anesthetized patients. Bacterial growth from superficial specimens, such as nasal discharge or swabs inserted into the external nares of unanesthetized patients, is unlikely to be clinically significant. It is difficult for a culture swab to be passed into the caudal nasal cavity without its being contaminated with superficial (insignificant) organisms. Guarded specimen swabs can prevent contamination but are relatively expensive. Alternatively, mucosal biopsies from the caudal nasal cavity can be obtained for culture using sterilized biopsy forceps; the results may be more indicative of true infection than those from swabs because, in theory, the organisms have invaded the tissues. Superficial contamination may still occur.

Regardless of the method used, the growth of many colonies of one or two types of bacteria more likely reflects infection than the growth of many different organisms. The microbiology laboratory should be asked to report all growth. Otherwise, the laboratory may report only one or two organisms that are more often pathogenic and provide misleading information about the relative purity of the culture. The presence of septic inflammation based on histologic examination of nasal specimens and a positive response to antibiotic therapy support a diagnosis of bacterial infection contributing to clinical signs. Although bacterial rhinitis is rarely a primary disease entity, improvement in nasal discharge may be seen if the bacterial component of the problem is treated; however, the improvement is generally transient unless the underlying disease process can be corrected. Some animals in which a primary disease process is never identified or cannot be corrected (e.g., cats with chronic rhinosinusitis) respond well to long-term antibiotic therapy. Sensitivity data from bacterial cultures considered to represent significant infection may help in antibiotic selection. (See Chapter 15 for further therapeutic recommendations.)

The role of *Mycoplasma* spp. in respiratory tract infections of dogs and cats is still being elucidated. Cultures for *Mycoplasma* spp. and treatment with appropriate antibiotics are a consideration for cats with chronic rhinosinusitis.

A diagnosis of nasal aspergillosis or penicilliosis requires the presence of several supportive signs, and fungal cultures are indicated whenever fungal disease is one of the differential diagnoses. The growth of Aspergillus or Penicillium organisms is considered along with other clinical data, such as radiographic and rhinoscopic findings, and serologic titers. Fungal growth supports a diagnosis of mycotic rhinitis only when other data also support the diagnosis. The fact that fungal infection occasionally occurs secondary to nasal tumors should not be overlooked during initial evaluation and monitoring of therapeutic response. The sensitivity of fungal culture can be greatly enhanced by collecting a swab or biopsy for culture directly from a fungal plaque or granuloma with rhinoscopic guidance.

#### FELINE UPPER RESPIRATORY INFECTION

#### Etiology

Upper respiratory infections (URIs) are common in cats. Feline herpesvirus (FHV), also known as *feline rhinotracheitis virus*, and *feline calicivirus* (FCV), cause nearly 90% of these infections. *Bordetella bronchiseptica* and *Chlamydophila felis* (previously known as *Chlamydia psittaci*) are less commonly involved. Other viruses and *Mycoplasmas* may play a primary or secondary role, whereas other bacteria are considered secondary pathogens.

Cats become infected through contact with actively infected cats, carrier cats, and fomites. Cats that are young, stressed, or immunosuppressed are most likely to develop clinical signs. Infected cats often become carriers of FHV or FCV after resolution of the clinical signs. The duration of the carrier state is not known but may last from weeks to years. *Bordetella* can be isolated from asymptomatic cats, although the effectiveness of transmission of disease from such cats is not known.

#### **Clinical Features**

Clinical manifestations of feline URI can be acute, chronic and intermittent, or chronic and persistent. Acute disease is the most common. The clinical signs of acute URI include fever, sneezing, serous or mucopurulent nasal discharge, conjunctivitis and ocular discharge, hypersalivation, anorexia, and dehydration. FHV can also cause corneal ulceration, abortion, and neonatal death, whereas FCV can cause oral ulcerations, mild interstitial pneumonia, or polyarthritis. Rare, short-lived outbreaks of highly virulent strains of calicivirus have been associated with severe upper respiratory disease, signs of systemic vasculitis (facial and limb edema progressing to focal necrosis) and high rates of mortality. Bordetella can cause cough and, in young kittens, pneumonia. Signs of Chlamydophila infection are usually limited to conjunctivitis.

Some cats that recover from the acute disease have periodic recurrence of acute signs, usually in association with stressful or immunosuppressive events. Other cats may have chronic, persistent signs, most notably a serous to mucopurulent nasal discharge with or without sneezing. Chronic nasal discharge can presumably result from persistence of an active viral infection or from irreversible damage to turbinates and mucosa by FHV; the latter predisposes the cat to an exaggerated response to irritants and secondary bacterial rhinitis. Unfortunately, correlation between tests to confirm exposure to or the presence of viruses and clinical signs is poor (Johnson et al., 2005). Because the role of viral infection in cats with chronic rhinosinusitis is not well understood, cats with chronic signs of nasal disease are discussed in the section on feline chronic rhinosinusitis (p. 232).

#### Diagnosis

Acute URI is usually diagnosed on the basis of history and physical examination findings. Specific tests that are available to identify FHV, FCV, *Bordetella*, and *Chlamydophila* organisms include fluorescent antibody testing, virus isolation procedures or bacterial cultures, polymerase chain reaction (PCR), and serum antibody titers. Fluorescent antibody tests for FHV and FCV are performed on smears prepared from conjunctival scrapings, pharyngeal swabs, or tonsillar

swabs or on impression smears from tonsillar biopsy specimens. Virus isolation tests and PCR can be performed on pharyngeal, conjunctival, or nasal swabs (using sterile swabs made of cotton) or on tissue specimens such as tonsillar biopsy specimens or mucosal scraping. Tissue specimens are preferred for virus isolation and PCR. Specimens are placed in appropriate transport media. Routine cytologic preparations of conjunctival smears can be examined for intracytoplasmic inclusion bodies suggestive of Chlamydophila infections, but these findings are nonspecific. Although routine bacterial cultures of the oropharynx can be used to identify Bordetella, the organism can be found in healthy and infected cats. Demonstration of rising antibody titers against a specific agent over 2 to 3 weeks suggests active infection. Regardless of the method used, close coordination with the pathology laboratory on specimen collection and handling is recommended for optimal results.

Tests to identify specific agents are particularly useful in cattery outbreaks in which the clinician is asked to recommend specific preventive measures. Multiple cats, both with and without clinical signs, should be tested when performing cattery surveys. Specific diagnostic tests are less useful for testing individual cats because their results do not alter therapy; false-negative results may occur if signs are the result of permanent nasal damage or if the specimen does not contain the agent, and, positive results may merely reflect a carrier cat that has a concurrent disease process causing the clinical signs. The exception to this generalization is individual cats with suspected *Chlamydophila* infection, in which case specific effective therapy can be recommended.

#### **Treatment**

In most cats URI is a self-limiting disease, and treatment of cats with acute signs includes appropriate supportive care. Hydration and nutritional needs should be provided when necessary. Dried mucus and exudate should be cleaned from the face and nares. The cat can be placed in a steamy bathroom or a small room with a vaporizer for 15 to 20 minutes two or three times daily to help clear excess secretions. Severe nasal congestion is treated with pediatric topical decongestants such as 0.25% phenylephrine or 0.025% oxymetazoline. A drop is gently placed in each nostril daily for a maximum of 3 days. If longer therapy is necessary, the decongestant is withheld for 3 days before beginning another 3-day course to prevent possible rebound congestion after withdrawal of the drug (based on problems with rebound congestion that occurs in people). Another option for prolonged decongestant therapy is to alternate daily the naris treated.

Antibiotic therapy to treat secondary infection is indicated in cats with severe clinical signs. The initial antibiotic of choice is ampicillin (22 mg/kg q8h) or amoxicillin (22 mg/kg q8h to q12h), because they are often effective, are associated with few adverse reactions, and can be administered to kittens. If *Bordetella*, *Chlamydophila*, or *Mycoplasma* spp. is suspected, doxycycline (5 to 10 mg/kg q12h, followed by a bolus of water) or chloramphenicol (10 to 15 mg/kg q12h) should be used. Azithromycin (5 to 10 mg/kg q24h for 3

days, then q72h) can be prescribed for cats that are difficult to medicate.

Cats with FHV infection may benefit from treatment with lysine. It has been postulated that excessive concentrations of lysine may antagonize arginine, a promoter of herpesvirus replication. Lysine (500 mg/cat q12h), obtained from health food stores, is added to food. Administration of feline recombinant omega interferon or human recombinant  $\alpha$ -2b interferon may also be of some benefit in FHV-infected cats (Siebeck et al., 2006).

Chlamydophila infection should be suspected in cats with conjunctivitis as the primary problem and in cats from catteries in which the disease is endemic. Oral antibiotics are administered for 3 weeks. In addition, chloramphenicol or tetracycline ophthalmic ointment should be applied at least three times daily and continued for a minimum of 14 days after the resolution of signs.

Corneal ulcers resulting from FHV are treated with topical antiviral drugs, such as trifluridine, idoxuridine, or adenine arabinoside. One drop should be applied to each affected eye five to six times daily for no longer than 2 to 3 weeks. Routine ulcer management is also indicated. Tetracycline or chloramphenicol ophthalmic ointment is administered two to four times daily. Topical atropine is used for mydriasis as needed to control pain. Treatment is continued for 1 to 2 weeks after epithelialization has occurred.

Topical and systemic corticosteroids are contraindicated in cats with acute URI or ocular manifestations of FHV infection. They can prolong clinical signs and increase viral shedding.

Treatment of cats with chronic signs is discussed on p. 233.

# Prevention in the Individual Pet Cat

Prevention of URI in all cats is based on avoiding exposure to the infectious agents (e.g., FHV, FCV, Bordetella and Chlamydophila organisms) and strengthening immunity against infection. Most household cats are relatively resistant to prolonged problems associated with URIs, and routine health care with regular vaccination using a subcutaneous product is adequate. Vaccination decreases severity of clinical signs resulting from URIs but does not prevent infection. Owners should be discouraged from allowing their cats to roam freely outdoors.

Subcutaneous modified-live virus vaccines for FHV and FCV are used for most cats and are available in combination with panleukopenia vaccine. These vaccines are convenient to administer, do not result in clinical signs when used correctly, and provide adequate protection for cats that are not heavily exposed to these viruses. These vaccines are not effective in kittens while maternal immunity persists. Kittens are usually vaccinated beginning at 6 to 10 weeks of age and again in 3 to 4 weeks. At least two vaccines must be given initially, with the final vaccine administered after the kitten is 16 weeks old. A booster vaccination is recommended 1 year after the final vaccine in the initial series. Subsequent booster vaccinations are recommended every 3 years, unless

the cat has increased risk of exposure to infection. A study by Lappin et al. (2002) indicates that detection of FHV and FCV antibodies in the serum of cats is predictive of susceptibility to disease and therefore may be useful in determining need for revaccination. Queens should be vaccinated before breeding.

Subcutaneous modified-live vaccines for FHV and FCV are safe but can cause disease if introduced into the cat by the normal oronasal route of infection. The vaccine should not be aerosolized in front of the cat. Vaccine inadvertently left on the skin after injection should be washed off immediately before the cat licks the area.

Modified-live vaccines should not be used in pregnant queens. Killed products are available for FHV and FCV that can be used in pregnant queens. Killed vaccines have also been recommended for cats with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) infection.

Modified-live vaccines for FHV and FCV are also available for intranasal administration. Signs of acute URI occasionally occur after vaccination. Attention should be paid to ensure that panleukopenia is included in the intranasal product or that a panleukopenia vaccine is administered subcutaneously.

Vaccines against *Bordetella* or *Chlamydophila* are recommended for use only in catteries or shelters where these infections are endemic. Infections with *Bordetella* or *Chlamydophila* are less common than FHV and FCV infection, and disease resulting from *Bordetella* infections occurs primarily in cats housed in crowded conditions. Furthermore, these diseases can be effectively treated with antibiotics.

#### **Prognosis**

The prognosis for cats with acute URI is good. Chronic disease does not develop in most pet cats.

#### **BACTERIAL RHINITIS**

Acute bacterial rhinitis caused by *Bordetella bronchiseptica* occurs occasionally in cats (see the section on feline upper respiratory infection) and rarely in dogs (see the section on canine infectious tracheobronchitis in Chapter 21). It is possible that *Mycoplasma* can act as primary nasal pathogens. In the vast majority of cases, bacterial rhinitis is a *secondary* complication and not a primary disease process. Bacterial rhinitis occurs secondarily to almost all diseases of the nasal cavity. The bacteria that inhabit the nasal cavity in health are quick to overgrow when disease disrupts normal mucosal defenses. Antibiotic therapy often leads to clinical improvement, but the response is usually temporary. Therefore management of dogs and cats with suspected bacterial rhinitis should include a thorough diagnostic evaluation for an underlying disease process, particularly when signs are chronic.

#### **Diagnosis**

Most dogs and cats with bacterial rhinitis have mucopurulent nasal discharge. No clinical signs are pathognomonic for

bacterial rhinitis, and it is difficult to make a definitive diagnosis because of the diverse flora in the normal nasal cavity (see Chapter 14). Microscopic evidence of neutrophilic inflammation and bacteria is a nonspecific finding in the majority of animals with nasal signs (Fig. 15-1). Bacterial cultures of swabs or nasal mucosal biopsies collected deep within the nasal cavity can be performed. The growth of many colonies of only one or two organisms may represent significant infection. Growth of many different organisms or small numbers of colonies probably represents normal flora. The microbiology laboratory should be requested to report all growth. Specimens for Mycoplasmal cultures should be placed in appropriate transport media for culture using specific isolation methods. Beneficial response to antibiotic therapy is often used to support a diagnosis of bacterial involvement.

#### **Treatment**

The bacterial component of nasal disease is treated with antibiotic therapy. If growth obtained by bacterial culture is believed to be significant, sensitivity information can be used in selecting antibiotics. Anaerobic organisms may be involved. Broad-spectrum antibiotics that may be effective include amoxicillin (22 mg/kg q8-12h), trimethoprim-sulfadiazine (15 mg/kg q12h), chloramphenicol (50 mg/kg q8h for dogs; 10 to 15 mg/kg q12h for cats), or clindamycin (5.5 to 11 mg/kg q12h). Doxycycline (5 to 10 mg/kg q12h, followed by a bolus of water) or chloramphenicol is often effective against *Bordetella* and *Mycoplasma* organisms.

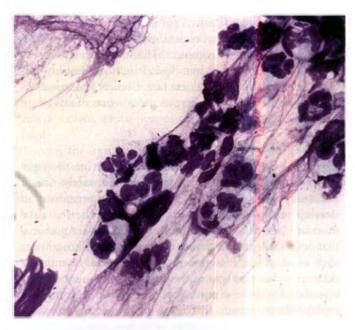

FIG 15-1

A photomicrograph of a slide prepared from a nasal swab of a patient with chronic mucopurulent discharge shows the typical findings of mucus, neutrophilic inflammation, and intracellular and extracellular bacteria. These findings are not specific and generally reflect secondary processes.

For acute infection or in cases in which the primary etiology (e.g., foreign body, diseased tooth root) has been eliminated, antibiotics are administered for 7 to 10 days. Chronic infections require prolonged treatment. Antibiotics are administered initially for 1 week. If a beneficial response is seen, the drug is continued for a minimum of 4 to 6 weeks. If signs recur after discontinuation of drug after 4 to 6 weeks, the same antibiotic is reinstituted for even longer periods.

If no response is seen after the initial week of treatment, the drug should be discontinued. Another antibiotic can be tried, although further evaluation for another, as yet unidentified, primary disorder should be pursued. Further diagnostic evaluation is particularly warranted in dogs because, compared with cats, they less frequently have idiopathic disease. Frequent stopping and starting of different antibiotics every 7 to 14 days is not recommended and may predispose the animal to the growth of resistant gram-negative infections.

#### **Prognosis**

Bacterial rhinitis is usually responsive to antibiotic therapy. However, long-term resolution of signs depends on the identification and correction of any underlying disease process.

#### NASAL MYCOSES

#### **CRYPTOCOCCOSIS**

Cryptococcus neoformans is a fungal agent that infects cats and, less commonly, dogs. It most likely enters the body through the respiratory tract and, in some animals, may disseminate to other organs. In cats clinical signs usually reflect infection of the nasal cavity, central nervous system (CNS), eyes, or skin and subcutaneous tissues. In dogs signs of CNS involvement are most common. The lungs are commonly infected in both species, but clinical signs of lung involvement (e.g., cough, dyspnea) are rare. Clinical features, diagnosis, and treatment of cryptococcosis are discussed in Chapter 98.

#### **ASPERGILLOSIS**

Aspergillus fumigatus is a normal inhabitant of the nasal cavity in many animals. In some dogs and, rarely, cats, it becomes a pathogen. The mold form of the organism can develop into visible fungal plaques that invade the nasal mucosa ("fungal mats") and fungal granulomas. An animal that develops aspergillosis may have another nasal condition, such as neoplasia, foreign body, prior trauma, or immune deficiency that predisposes the animal to secondary fungal infection. Excessive exposure to Aspergillus organisms may explain the frequent occurrence of disease in otherwise healthy animals. Another type of fungus, Penicillium, can cause signs similar to those of aspergillosis.

#### **Clinical Features**

Aspergillosis can cause chronic nasal disease in dogs of any age or breed but is most common in young male dogs. Nasal

infection is rare in cats. The discharge can be mucoid, mucopurulent with or without hemorrhage, or purely hemorrhagic. The discharge can be unilateral or bilateral. Sneezing may be reported. Features that are highly suggestive of aspergillosis are sensitivity to palpation of the face or depigmentation and ulceration of the external nares (see Fig. 13-1). Lung involvement is not expected.

Systemic aspergillosis in dogs is generally caused by *Aspergillus terreus* and other *Aspergillus* spp. rather than *A. fumigatus*. It is an unusual, generally fatal disease that occurs primarily in German Shepherd Dogs. Nasal signs are not reported.

#### Diagnosis

No single test result is diagnostic for infection with aspergillosis. The diagnosis is based on the cumulative findings of a comprehensive evaluation of a dog with appropriate clinical signs. In addition, aspergillosis can be an opportunistic infection, and underlying nasal disease must always be considered.

Radiographic signs of aspergillosis include well-defined lucent areas within the nasal cavity and increased radiolucency rostrally (see Fig. 14-7). Typically no destruction of the vomer or facial bones occurs, although the bones may appear roughened. However, destruction of these bones or the cribriform plate may occur in dogs with advanced disease. Increased fluid opacity may be present. Fluid opacity within the frontal sinus can represent a site of infection or mucus accumulation from obstructed drainage. In some patients the frontal sinus is the only site of infection.

Rhinoscopic abnormalities include erosion of nasal turbinates and fungal plaques, which appear as white-to-green plaques of mold on the nasal mucosa (see Fig. 14-13). Failure to visualize these lesions does not rule out aspergillosis. Confirmation that presumed plaques are indeed fungal hyphae can be achieved by cytology (Fig. 15-2) and culture of material collected by biopsy or swab under visual guidance. During rhinoscopy, plaques are mechanically debulked by

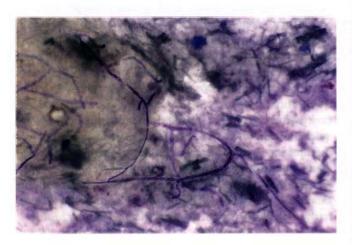

FIG 15-2
Branching hyphae of Aspergillus fumigatus from a swab of a visualized fungal plaque.

scraping or vigorous flushing to increase the efficacy of topical treatment.

Aspergillus organisms can generally be seen histologically in biopsy specimens of affected nasal mucosa after routine staining techniques, although special staining can be performed to identify subtle involvement. Neutrophilic, lymphoplasmacytic, or mixed inflammation is usually also present. Multiple biopsy specimens should be obtained because the mucosa is affected multifocally rather than diffusely. Invasion of fungal organisms into the nasal mucosa is indicative of infection.

Results of fungal cultures are difficult to interpret, unless the specimen is obtained from a visualized plaque. The organism can be found in the nasal cavity of normal animals, and false-negative culture results can also occur. A positive culture, in conjunction with other appropriate clinical and diagnostic findings, supports the diagnosis.

Positive serum antibody titers also support a diagnosis of infection. Although titers are indirect evidence of infection, animals with *Aspergillus* organisms as a normal nasal inhabitant do not usually develop measurable antibodies against the organism. Pomerantz et al. (2007) found that serum antibodies had a sensitivity of 67%, a specificity of 98%, a positive predictive value of 98%, and a negative predictive value of 84% for the diagnosis of nasal aspergillosis. Their study included 21 dogs with aspergillosis, 25 dogs with nonfungal rhinitis, and 12 dogs with nasal neoplasia.

#### **Treatment**

The current treatments of choice for nasal aspergillosis are topical clotrimazole, with a success rate of 80% to 90% with one or more treatments, and oral itraconazole, with a success rate of 60% to 70%. Oral therapy is simpler to administer than topical therapy but is somewhat less successful, requires prolonged treatment, and is relatively expensive. Itraconazole is administered orally at a dose of 5 mg/kg every 12 hours and must be continued for 60 to 90 days or longer. (See Chapter 98 for a complete discussion of this drug.)

Successful topical treatment of aspergillosis was originally documented with enilconazole administered through tubes placed surgically into both frontal sinuses and both sides of the nasal cavity. The drug was administered through the tubes twice daily for 7 to 10 days. Subsequently, it was discovered that the over-the-counter drug clotrimazole was equally efficacious when infused through surgically placed tubes over a 1-hour period. During the 1-hour infusion, the dogs were kept under anesthesia and the caudal nasopharynx and external nares were packed to allow filling of the nasal cavity. It has since been demonstrated that good distribution of the drug can be achieved using a noninvasive technique (discussed in the next paragraphs). Success with clotrimazole using this technique has been similar to that documented with infusion through surgically placed tubes. Debridement of visible fungal plaques during rhinoscopy and before topical therapy appears to increase the rate of success.

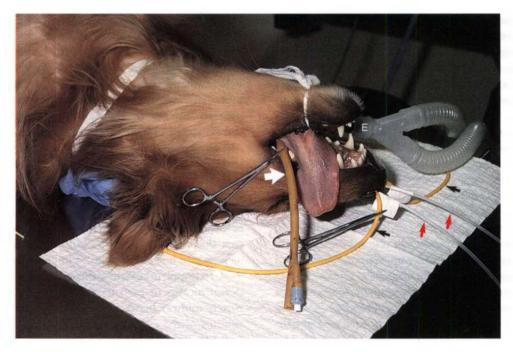

The animal is anesthetized and oxygenated through a cuffed endotracheal tube. The dog is positioned in dorsal recumbency with the nose pulled down parallel with the table (Figs. 15-3 and 15-4). For a large-breed dog, a 24 Fr Foley catheter with a 5-ml balloon is passed through the oral cavity, around the soft palate, and into the caudal nasopharynx such that the bulb is at the junction of the hard and soft palates. The bulb is inflated with approximately 10 ml of air to ensure a snug fit. A laparotomy sponge is inserted within the oropharynx, caudal to the balloon and ventral to the soft palate to help hold the balloon in position and further obstruct the nasal pharynx. Additional laparotomy sponges are packed carefully into the back of the mouth around the tracheal tube to prevent any drug that might leak past the nasopharyngeal packing from reaching the lower airways.

A 10 Fr polypropylene urinary catheter is passed into the dorsal meatus of each nasal cavity to a distance approximately midway between the external naris and the medial canthus of the eye. The correct distance is marked on the catheters with tape to prevent accidentally inserting the catheters too far during the procedure. A 12 Fr Foley catheter with a 5-ml balloon is passed adjacent to the polypropylene catheter into each nasal cavity. The cuff is inflated and pulled snugly against the inside of the naris. A small suture is placed across each naris lateral to the catheter to prevent balloon migration. A gauze sponge is placed between the endotracheal tube and the incisive ducts behind the upper incisors to minimize leakage.

A solution of 1% clotrimazole is administered through the polypropylene catheters. Approximately 30 ml is used for each side in a typical retriever-size dog. Each Foley catheter is checked for filling during the initial infusion and is then clamped when clotrimazole begins to drip from the catheter. The solution is viscous, but excessive pressure is not required for infusion. Additional clotrimazole is administered during the next hour at a rate that results in approximately 1 drop every few seconds from each external naris. In dogs of the size described, a total of approximately 100 to 120 ml will be used.

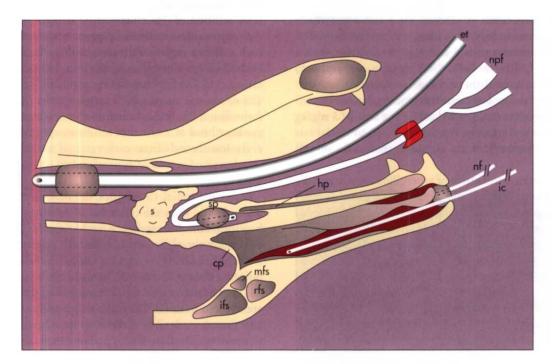

After the initial 15 minutes, the head is tilted slightly to one side and then the other for 15 minutes each and then back into dorsal recumbency for 15 minutes. After this hour of contact time, the dog is rolled into sternal recumbency with the head hanging over the end of the table and the nose pointing toward the floor. The catheters are removed from the external nares, and the clotrimazole and resulting mucus are allowed to drain. Drainage will usually subside in 10 to 15 minutes. A flexible suction tip may be used to expedite this process. The laparotomy pads are then carefully removed from the nasopharynx and oral cavity and counted to ensure that all are retrieved. The catheter in the nasopharynx is removed. Any drug within the oral cavity is swabbed or suctioned.

Two potential complications of clotrimazole treatment are aspiration pneumonia and meningoencephalitis. Meningoencephalitis is generally fatal and results when clotrima-

#### FIG 15-3

Dog with nasal mycotic infection prepared for 1-hour soak with clotrimazole. A cuffed endotracheal tube is in place (E). A 24 Fr Foley catheter (broad arrow) is in the caudal nasopharynx. A 12 Fr Foley catheter (narrow arrows) is obstructing each nostril. A 10 Fr polypropylene catheter (red arrowheads) is placed midway into each dorsal meatus for infusion of the drug. Laparotomy sponges are used to further pack the caudal nasopharynx, around the tracheal tube and the caudal oral cavity.

#### FIG 15-4

(Reprinted with permission from Mathews KG et al: Computed tomographic assessment of noninvasive intranasal infusions in dogs with fungal rhinitis, Vet Surg 25:309, 1996.)

zole and its carrier, polyethylene glycol (PEG), make contact with the brain through a compromised cribriform plate. It is difficult to determine the integrity of the cribriform plate before treatment without the aid of computed tomography (CT) or magnetic resonance imaging (MRI), although marked radiographic changes in the caudal nasal cavity should increase concern. Fortunately, complications are not common.

Clinical signs generally resolve in 1 to 2 weeks. A second 1-hour soak is performed if signs persist after 2 weeks. One cause of treatment failure is the inability of clotrimazole to reach all sites of infection. As previously mentioned, removal of fungal plaques with rhinoscopic guidance is thought to improve response to therapy. One or both frontal sinuses are often infected, and it may be necessary to trephine the affected sinus, debulk any fungal granulomas, and directly administer clotrimazole into the sinus. In rare cases, infection extends beyond the nasal cavity (e.g., into the retrobulbar space). Itraconazole treatment is indicated in these patients.

Some clinicians have had success using the combination of itraconazole and another oral antifungal agent, terbinafine, for the treatment of aspergillosis. Published studies are not available (see Chapter 98).

Some dogs have a persistant nasal discharge after treatment for aspergillosis in the absence of identifiable active fungal infection. These dogs may have secondary bacterial rhinitis or sensitivity to inhaled irritants because of the damaged nasal anatomy and mucosa and are managed as described in the section on canine chronic/lymphoplasmacytic rhinitis in this chapter.

#### **Prognosis**

The prognosis for dogs with nasal aspergillosis has improved with the availability of new antifungal agents. For most animals a fair-to-good prognosis is warranted.

#### NASAL PARASITES

#### **NASAL MITES**

Pneumonyssoides caninum is a small white mite approximately 1 mm in size (see Fig. 14-14, A). Most infestations are clinically silent, but some dogs may have moderate-to-severe clinical signs.

#### **Clinical Features and Diagnosis**

A common clinical feature of nasal mites is sneezing, which is often violent. Head shaking, pawing at the nose, reverse sneezing, chronic nasal discharge, and epistaxis can also occur. These signs are similar to those caused by nasal foreign bodies. The diagnosis is made by visualizing the mites during rhinoscopy or by retrograde nasal flushing, as described in Chapter 14. The mites can be easily overlooked in the retrieved saline solution; they should be specifically searched for with slight magnification or by placing dark material behind the specimen for contrast. Further, the mites are

often located in the frontal sinuses and caudal nasal cavity. Marks et al. (1994) report the greatest success in identifying mites by flushing the nasal cavities with halothane in oxygen. The anesthetic mixture causes the mites to migrate to the caudal nasopharynx, where the mites are visualized using an endoscope.

#### **Treatment**

Milbemycin oxime (0.5 to 1 mg/kg, orally, every 7 to 10 days for three treatments) has been used successfully for treating nasal mites. Ivermectin has also been used for treatment (0.2 mg/kg, administered subcutaneously and repeated in 3 weeks), but it is not safe for certain breeds. Any dogs in direct contact with the affected animal should also be treated.

#### **Prognosis**

The prognosis for dogs with nasal mites is excellent.

#### NASAL CAPILLARIASIS

Nasal capillariasis is caused by a nematode, Capillaria (Eucoleus) boehmi, originally identified as a worm of the frontal sinuses in foxes. The adult worm is small, thin, and white and lives on the mucosa of the nasal cavity and frontal sinuses of dogs (see Fig. 14-14, B). The adults shed eggs that are swallowed and pass in the feces. Clinical signs include sneezing and mucopurulent nasal discharge, with or without hemorrhage. The diagnosis is made by identifying double operculated Capillaria (Eucoleus) eggs on routine fecal flotation (similar to the eggs of Capillaria (Eucoleus) aerophila; see Fig. 20-12, C) or visualizing adult worms during rhinoscopy. Treatments include ivermectin (0.2 mg/kg, orally, once) or fenbendazole (25 to 50 mg/kg q12h for 10 to 14 days). Success of treatment should be confirmed with repeated fecal examinations, in addition to resolution of clinical signs. Repeated treatments may be necessary, and reinfection is possible if exposure to contaminated soil continues.

#### NASOPHARYNGEAL POLYPS

Nasopharyngeal polyps are benign growths that occur most often in kittens and young adult cats, although they are occasionally found in older animals. Their origin is unknown, but they are often attached to the base of the eustachian tube. They can extend into the external ear canal, middle ear, pharynx, and nasal cavity. Grossly, they are pink, polypoid growths, often arising from a stalk (Fig. 15-5). Because of their gross appearance, they are sometimes mistaken for neoplasia.

#### **Clinical Features**

Respiratory signs caused by nasopharyngeal polyps include stertorous breathing, upper airway obstruction, and serousto-mucopurulent nasal discharge. Signs of otitis externa or otitis media/interna, such as head tilt, nystagmus, or Horner's syndrome, can also occur.

FIG 15-5

A nasopharyngeal polyp was visualized during rhinoscopy through the exterior naris of a cat with chronic nasal discharge. The polyp was excised by traction and has an obvious stalk.

#### **Diagnosis**

Identification of a soft tissue opacity above the soft palate radiographically and gross visualization of a mass in the nasopharynx, nasal cavity, or external ear canal support a tentative diagnosis of nasopharyngeal polyp. Complete evaluation of cats with polyps also includes a deep otoscopic examination and radiographs or CT scans of the osseous bullae to determine the extent of involvement. The majority of cats with polyps have otitis media, detectable radiographically as thickened bone or increased soft tissue opacity of the bulla (see Fig. 14-6). The definitive diagnosis is made by histopathologic analysis of tissue biopsy; the specimen is usually obtained during surgical excision. Nasopharyngeal polyps are composed of inflammatory tissue, fibrous connective tissue, and epithelium.

#### **Treatment**

Treatment of nasopharyngeal polyps consists of surgical excision. Surgery is usually performed through the oral cavity by traction. In addition, bullae osteotomy should be considered in cats with radiographic or CT evidence of involvement of the osseous bullae. Rarely, rhinotomy is required for complete removal.

An early study by Kapatkin et al. (1990) reported that 5 of 31 cats had regrowth of an excised polyp. Of the five cats with regrowth, four had not had bulla osteotomies. These findings support the importance of addressing involvement of the osseous bulla in cats with polyps. However, a subsequent study by Anderson et al. (2000) reported successful treatment with traction alone, particularly when followed by

a course of prednisolone in some cats. Prednisolone was administered at 1 to 2 mg/kg every 24 hours for 2 weeks, then at half the original dose for 1 week, then every other day for 7 to 10 more days. A course of antibiotics (e.g., amoxicillin) was also administered.

#### **Prognosis**

The prognosis is excellent, but treatment of recurrent disease may be necessary. Regrowth of a polyp can occur at the original site if abnormal tissue remains, with signs of recurrence typically appearing within 1 year. Bulla osteotomies should be considered in cats with recurrence and signs of otitis media if not performed with initial treatment.

#### **NASAL TUMORS**

The majority of nasal tumors in the dog and cat are malignant. Adenocarcinoma, squamous cell carcinoma, and undifferentiated carcinoma are common nasal tumors in dogs. Lymphoma and adenocarcinoma are common in cats. Fibrosarcomas and other sarcomas also occur in both species. Benign tumors include adenomas, fibromas, papillomas, and transmissible venereal tumors (the latter only in dogs).

#### **Clinical Features**

Nasal tumors usually occur in older animals but cannot be excluded from the differential diagnosis of young dogs and cats. No breed predisposition has been consistently identified. Collies and Irish Setters were overrepresented in a report of malignant nasal tumors in dogs by Evans et al. (1989).

The clinical features of nasal tumors (usually chronic) reflect the locally invasive nature of these tumors. Nasal discharge is the most common complaint. The discharge can be serous, mucoid, mucopurulent, or hemorrhagic. One or both nostrils can be involved. With bilateral involvement, the discharge is often worse from one nostril compared with the other. For many animals the discharge is initially unilateral and progresses to bilateral. Sneezing may be reported. Obstruction of the nasal cavity by the tumor may cause decreased or absent air flow through one of the nares.

Deformation of the facial bones, hard palate, or maxillary dental arcade may be visible (see Fig. 13-4). Tumor growth extending into the cranial vault can result in neurologic signs. Growth into the orbit may cause exophthalmos or inability to retropulse the eye. Animals only rarely experience neurologic signs (e.g., seizures, behavior changes, abnormal mental status) or ocular abnormalities as the primary complaints (i.e., no signs of nasal discharge). Weight loss and anorexia may accompany the respiratory signs but are often absent.

#### Diagnosis

A diagnosis of neoplasia is based on clinical features and supported by typical abnormalities detected by imaging of the nasal cavity and frontal sinuses or rhinoscopy. A definitive diagnosis requires histopathologic examination of a biopsy specimen, although fine needle aspirates of nasal masses may provide conclusive results. Imaging (radiography, CT, or MRI) and rhinoscopic abnormalities can reflect soft tissue mass lesions; turbinate, vomer bone, or facial bone destruction (see Figs. 14-2, 14-4, and 14-8, *B*); or diffuse infiltration of the mucosa with neoplastic and inflammatory cells.

Biopsy specimens, including tissue from deep within the lesion, should be obtained in all patients for histologic confirmation. Nasal neoplasms frequently cause a marked inflammatory response of the nasal mucosa and, in some patients, secondary bacterial or fungal infection. A cytologic diagnosis of neoplasia must be accepted cautiously, taking into consideration concurrent inflammation and potentially marked hyperplastic and metaplastic change. Furthermore, in some cases the cytologic characteristics of lymphoma and carcinoma will mimic each other, which may lead to an erroneous classification.

Not all cases of neoplasia will be diagnosed on initial evaluation of the dog or cat. Imaging, rhinoscopy, and biopsy may need to be repeated in 1 to 3 months in animals with persistent signs in which a definitive diagnosis has not been made. CT and MRI are more sensitive techniques for imaging nasal tumors than routine radiography, and one of these should be performed when available (see Fig. 14-8, *B*). Surgical exploration is occasionally necessary to obtain a definitive diagnosis.

Once a definitive diagnosis is made, determining the extent of disease can help in assessing the feasibility of surgical or radiation therapy versus chemotherapy. Some information can be obtained from high-quality nasal radiographs, but CT and MRI are more sensitive methods for evaluating the extent of abnormal tissue. Aspirates of mandibular lymph nodes should be examined cytologically for evidence of local spread. Thoracic radiographs are evaluated, although pulmonary metastases are uncommon at the time of initial diagnosis. Cytologic evaluation of bone marrow aspirates and abdominal radiographs or ultrasound are indicated for patients with lymphoma. Cats with lymphoma are also tested for Fel.V and FIV.

#### **Treatment**

Treatment of benign tumors should include surgical excision. Malignant nasal tumors can be treated with radiation therapy (with or without surgery) and/or chemotherapy. Palliative treatment can also be tried. The treatments of choice for cats with nasal lymphoma are chemotherapy using standard lymphoma protocols (see Chapter 80), radiation therapy, or both. Radiation therapy avoids the systemic adverse effects of chemotherapeutic drugs but may be insufficient if the tumor involves other organs.

Radiation therapy is the treatment of choice for most other malignant nasal tumors. Surgical debulking before radiation is recommended if orthovoltage radiation will be used. Surgery is not beneficial before megavoltage radiation (cobalt or linear accelerator), but improved success of treatment has been recently reported with surgical debulking performed after megavoltage radiotherapy (Adams et al., 2005).

Treatment of malignant nasal tumors with surgery alone does not result in prolonged survival times; it may indeed shorten survival times. It is doubtful that all abnormal tissue can be excised in the majority of cases.

Chemotherapy may be attempted when radiation therapy has failed or is not a viable option. Carcinomas may be responsive to cisplatin, carboplatin, or multiagent chemotherapy. (See Chapter 77 for a discussion of general principles for the selection of chemotherapy.)

Treatment with piroxicam, a nonsteroidal antiinflammatory drug, can be considered for dogs with carcinoma for which radiation therapy is not elected. Partial remissions or improvement in clinical signs have been reported for some dogs with transitional cell carcinoma of the urinary bladder, oral squamous cell carcinoma, and several other carcinomas. Potential side effects include gastrointestinal ulceration (which can be severe) and kidney damage. For dogs with other types of tumors and cats, improvement of clinical signs may be seen with antiinflammatory doses of glucocorticoids. Prednisolone is prescribed for cats, and either prednisone or prednisolone for dogs (0.5 to 1 mg/kg/day; tapered to lowest effective dose). Neither drug should be given in conjunction with piroxicam.

#### **Prognosis**

The prognosis for dogs and cats with untreated malignant nasal tumors is poor. Survival after diagnosis is usually only a few months. Euthanasia is often requested because of persistent epistaxis or discharge, labored respirations, anorexia and weight loss, or neurologic signs. Epistaxis is a poor prognostic indicator. In a study of 132 dogs with untreated nasal carcinoma by Rassnick et al. (2006), the median survival time of dogs with epistaxis was 88 days (95% confidence interval (CI), 65-106 days) and of dogs without epistaxis was 224 days (95% CI, 54-467 days). The overall median survival time was 95 days (range 7-1114 days).

Radiation therapy can prolong survival and improve quality of life in some animals. The therapy is well tolerated by most animals, and in those that achieve remission the quality of life is usually excellent. Studies of dogs treated with megavoltage radiation, with or without prior surgical treatment, by Theon et al. (1993) and Henry et al. (1998) found median survival times of approximately 13 months. Survival rates for 1 and 2 years were 55% to 60% and 25% to 45%, respectively. For dogs receiving megavoltage radiation followed by surgical debulking, median survival time was 47.7 months, with survival rates for 2 and 3 years of 69% and 58%, respectively (Adams et al., 2005). The dogs in the study by Adams et al. (2005) that did not receive postradiotherapy surgery had a median survival of 19.7 months and lower 2- and 3-year survival rates (44% and 24%, respectively).

A study by Evans et al. (1989) of dogs receiving orthovoltage radiation therapy after surgical debulking reported a median survival time of 16.5 months, a 1-year survival rate of 54% and a 2-year survival rate of 43%. Northrup et al. (2001)

report a median survival time of approximately 7 months, a 1-year survival rate of 37%, and a 2-year survival rate of only 17% in dogs treated with surgery and orthovoltage radiation.

Less information is available concerning prognosis in cats. According to Straw et al. (1986), six cats with malignant neoplasms (three with lymphoma) that received radiation therapy had a mean survival time of 19 months. A study by Theon et al. (1994) of 16 cats with nonlymphoid neoplasia receiving radiation therapy showed a 1-year survival rate of 44% and a 2-year survival rate of 17%. Of eight cats with nasal lymphoma treated with cyclophosphamide, vincristine, and prednisolone (COP), six (75%) achieved complete remission (Teske et al., 2002). Median survival time was 358 days, and the estimated 1-year survival rate was 75%. According to preliminary data from Arteaga et al. (2007), cats with nasal lymphoma treated with radiation and chemotherapy had a median survival time of 511 days.

#### ALLERGIC RHINITIS

#### Etiology

Allergic rhinitis has not been well characterized in dogs or cats. However, dermatologists provide anecdotal reports of atopic dogs rubbing the face (possibly indicating nasal pruritus) and experiencing serous nasal discharge, in addition to dermatologic signs. Allergic rhinitis is generally considered to be a hypersensitivity response within the nasal cavity and sinuses to airborne antigens. It is possible that food allergens play a role in some patients. Other antigens are capable of inducing a hypersensitivity response as well, and thus the differential diagnoses must include parasites, other infectious diseases, and neoplasia.

#### **Clinical Features**

Dogs or cats with allergic rhinitis experience sneezing and/or serous or mucopurulent nasal discharge. Signs may be acute or chronic. Careful questioning of the owner may reveal a relationship between signs and potential allergens. For instance, signs may be worse during certain seasons; in the presence of cigarette smoke; or after the introduction of a new brand of kitty litter, new perfumes, cleaning agents, furniture, or fabric in the house. Note that worsening of signs may simply be a result of exposure to irritants rather than an actual allergic response. Debilitation of the animal is not expected.

#### **Diagnosis**

Identifying a historical relationship between signs and a particular allergen and then achieving resolution of signs after removal of the suspected agent from the animal's environment support the diagnosis of allergic rhinitis. When this approach is not possible or successful, a thorough diagnostic evaluation of the nasal cavity is indicated (see Chapters 13 and 14). Nasal radiographs reveal increased soft tissue opacity with minimal or no turbinate destruction. Classically, nasal

biopsy reveals eosinophilic inflammation. It is possible that with chronic disease, a mixed inflammatory response occurs, obscuring the diagnosis. There should be no indication in any of the diagnostic tests of an aggressive disease process, parasites or other active infection, or neoplasia.

#### **Treatment**

Removing the offending allergen from the animal's environment or diet is the ideal treatment of allergic rhinitis. When this is not possible, a beneficial response may be achieved with antihistamines. Chlorpheniramine can be administered orally at a dose of 4 to 8 mg/dog every 8 to 12 hours or 2 mg/cat every 8 to 12 hours. The second-generation antihistamine cetirizine (Zyrtec, Pfizer) may be more successful in cats. A pharmacokinetic study of this drug in healthy cats found a dosage of 1 mg/kg, administered orally every 24 hours, to maintain plasma concentrations similar to those reported in people (Papich et al., 2006). Glucocorticoids may be used if antihistamines are unsuccessful. Prednisone is initiated at a dose of 0.25 mg/kg every 12 hours until signs resolve. The dose is then tapered to the lowest effective amount. If treatment is effective, signs will generally resolve within a few days. Drugs are continued only as long as needed to control signs.

#### **Prognosis**

The prognosis for dogs and cats with allergic rhinitis is excellent if the allergen can be eliminated. Otherwise, the prognosis for control is good, but a cure is unlikely.

#### IDIOPATHIC RHINITIS

Idiopathic rhinitis is a more common diagnosis in cats compared with dogs. The diagnosis cannot be made without a thorough diagnostic evaluation to rule out specific diseases (see Chapters 13 and 14).

#### FELINE CHRONIC RHINOSINUSITIS

#### Etiology

Feline chronic rhinosinusitis has long been presumed to be a result of viral infection with FHV or FCV (see the section on feline upper respiratory infection, p. 223). Persistent viral infection has been implicated, but studies have failed to show an association between tests indicating exposure to or infection with these viruses and clinical signs. It is possible that infection with these viruses results in damaged mucosa that is more susceptible to bacterial infection or that mounts an excessive inflammatory response to irritants or normal nasal flora. Preliminary studies have failed to show an association with feline chronic rhinosinusitis and *Bartonella* infection, based on serum antibody titers or PCR of nasal tissue (Berryessa et al., 2007). In the absence of a known etiology, this disease will be denoted by the term *idiopathic feline chronic rhinosinusitis*.

#### **Clinical Features and Diagnosis**

Chronic mucoid or mucopurulent nasal discharge is the most common clinical sign of idiopathic feline chronic rhinosinusitis. The discharge is typically bilateral. Fresh blood may be seen in the discharge of some cats but is not usually a primary complaint. Sneezing may occur. Given that this is an idiopathic disease, the lack of specific findings is important. Cats should have no funduscopic lesions, no lymphadenopathy, no facial or palate deformities, and healthy teeth and gums. Anorexia and weight loss are rarely reported. Thorough diagnostic testing is indicated, as described in Chapters 13 and 14. Results of such testing do not support the diagnosis of a specific disease. Usual nonspecific findings include turbinate erosion, mucosal inflammation, and increased mucus accumulation as assessed by nasal imaging and rhinoscopy; neutrophilic or mixed inflammation with bacteria on cytology of nasal discharge; and neutrophilic and/or lymphoplasmacytic inflammation on nasal biopsy. Nonspecific abnormalities attributable to chronic inflammation, such as epithelial hyperplasia and fibrosis, may also be seen. Secondary bacterial rhinitis or Mycoplasma infection may be identified.

#### **Treatment**

Cats with idiopathic chronic rhinosinusitis often require management for years. Fortunately, most of these cats are healthy in all other respects. Treatment strategies include facilitating drainage of discharge; decreasing irritants in the environment; controlling secondary bacterial infections; treating possible *Mycoplasmal* or FHV infection; reducing inflammation; and, as a last resort, performing a turbinectomy and frontal sinus ablation (Box 15-1).

Keeping secretions moist, performing intermittent nasal flushes, and judiciously using topical decongestants facilitate drainage. Keeping the cat in a room with a vaporizer, for instance, during the night, can provide symptomatic relief by keeping secretions moist. Alternatively, drops of sterile saline can be placed into the nares. Some cats experience a marked improvement in clinical signs for weeks after flushing of the nasal cavity with copious amounts of saline or dilute betadine solution. General anesthesia is required, and the lower airways must be protected with an endotracheal tube, gauze sponges, and positioning of the head to facilitate drainage from the external nares. Topical decongestants, as described for feline upper respiratory infection (see page 224), may provide symptomatic relief during episodes of severe congestion.

Irritants in the environment can further exacerbate mucosal inflammation. Irritants such as smoke (from tobacco or fireplace) and perfumed products should be avoided. Motivated clients can take steps to improve the air quality in their homes, such as by cleaning the carpet, furniture, drapery, and furnace; regularly replacing air filters; and using an air cleaner. The American Lung Association has a useful Web site with nonproprietary recommendations for improving indoor air quality (www.lungusa.org).

BOX 15-1

Management Considerations for Cats with Idiopathic Chronic Rhinosinusitis

#### Facilitate Drainage of Discharge

Vaporizer treatments
Topical saline administration
Nasal cavity flushes under anesthesia
Topical decongestants

#### Decrease Irritants in the Environment

Improvement of indoor air quality

#### **Control Secondary Bacterial Infections**

Long-term antibiotic treatment

#### Treat Possible Mycoplasma Infection

Antibiotic treatment

#### Treat Possible Herpesvirus Infection

Lysine treatment

#### Reduce Inflammation

Second-generation antihistamine treatment Oral prednisolone treatment

#### Surgical Intervention

Turbinectomy
Frontal sinus ablation

Chronic antibiotic therapy may be required to manage secondary bacterial infections. Broad-spectrum antibiotics such as amoxicillin (22 mg/kg q8-12h) or trimethoprimsulfadiazine (15 mg/kg q12h) are often successful. Chloramphenicol (10 to 15 mg/kg q12h) and doxycycline (5 to 10 mg/kg q12h, followed by a bolus of water) have activity against some bacteria and Chlamydophila and Mycoplasma organisms and can be effective in some cats when other drugs have failed. This author reserves fluoroquinolones for cats with documented resistant gram-negative infections. If a beneficial response to antibiotic therapy is seen within 1 week of its initiation, the antibiotic should be continued for at least 4 to 6 weeks. If a beneficial response is not seen, the antibiotic is discontinued. Note that the frequent stopping and starting of different antibiotics every 7 to 14 days is not recommended and may predispose the cat to resistant gramnegative infections. Cats that respond well during the prolonged course of antibiotics but that relapse shortly after discontinuation of the drug despite 4 to 6 weeks of relief are candidates for continuous long-term antibiotic therapy. Treatment with the previously used antibiotic often can be successfully reinstituted. Amoxicillin administered twice daily is often sufficient.

Treatment with lysine may be effective in cats with active herpesvirus infections. It has been postulated that

excessive concentrations of lysine may antagonize arginine, a promoter of herpesvirus replication. Because the specific organism(s) involved is rarely known, trial therapy is initiated. Lysine (500 mg/cat q12h), which can obtained from health food stores, is added to food. A minimum of 4 weeks is necessary to assess success of treatment.

Anecdotal success in occasional cats has been reported with treatment with the second-generation antihistamine cetirizine (Zyrtec, Pfizer) as described for allergic rhinitis (see p. 232). No efficacy studies are available.

Cats with severe signs that persist despite the previously described methods of supportive care may benefit from glucocorticoids to reduce inflammation. However, certain risks are involved. Glucocorticoids may further predispose the cat to secondary infections, increase viral shedding, and mask signs of a more serious disease. Glucocorticoids should be prescribed only after a complete diagnostic evaluation has been performed to rule out other diseases. Prednisolone is administered at a dose of 0.5 mg/kg every 12 hours. If a beneficial response is seen within 1 week, the dose is gradually decreased to the lowest effective dose. A dose as low as 0.25 mg/kg every 2 to 3 days may be sufficient to control clinical signs. If a clinical response is not seen within 1 week, the drug should be discontinued.

Cats with severe or deteriorating signs that persist despite conscientious care are candidates for turbinectomy and frontal sinus ablation, assuming a complete diagnostic evaluation to eliminate other causes of chronic nasal discharge has been performed (Chapters 13 and 14). Turbinectomy and frontal sinus ablation are difficult surgical procedures. Major blood vessels and the cranial vault must be avoided, and tissue remnants must not be left behind. Anorexia can be a postoperative problem; placement of an esophagostomy or gastrostomy tube (see p. 30) provides an excellent means for meeting nutritional requirements if necessary after surgery. Complete elimination of respiratory signs is unlikely, but signs may be more easily managed. The reader is referred to surgical texts by Fossum or Slatter for a description of the surgical techniques (see Suggested Readings).

#### CANINE CHRONIC/ LYMPHOPLASMACYTIC RHINITIS

#### **Etiology**

Idiopathic chronic rhinitis in dogs is sometimes characterized by the inflammatory infiltrates seen in nasal mucosal biopsies; thus the disease lymphoplasmacytic rhinitis has been described. It was originally reported to be a steroid-responsive disorder (Burgener et al., 1987), but a subsequent report by Windsor et al. (2004) and clinical experience suggest that corticosteroids are not always effective in the treatment of lymphoplasmacytic rhinitis. It is not uncommon for neutrophilic inflammation to be found, predominantly or along with lymphoplasmacytic infiltrates. For these reasons, the less specific term *idiopathic canine chronic rhinitis* will be used.

Many specific causes of nasal disease result in a concurrent inflammatory response because of the disease itself or as a response to the secondary effects of infection or enhanced response to irritants; this makes a thorough diagnostic evaluation of these cases imperative. Windsor et al. (2006) performed multiple PCR assays on paraffin-embedded nasal tissue from dogs with idiopathic chronic rhinitis and failed to find evidence for a role of bacteria (based on DNA load), canine adenovirus-2, parainfluenza virus, *Chlamydophila* spp. or *Bartonella* spp. in affected dogs. High amounts of fungal DNA were found in affected dogs, suggesting a possible contribution to clinical signs. Alternatively, the result may simply reflect decreased clearance of fungal organisms from the diseased nasal cavity.

Although not supported in the previously quoted study, a potential role for *Bartonella* infection has been suggested on the basis of a study that found an association between seropositivity for *Bartonella* spp. and nasal discharge or epistaxis (Henn et al., 2005) and a report of three dogs with epistaxis and evidence of infection with *Bartonella* spp. (Breitschwerdt et al., 2005). A study in our laboratory (Hawkins et al., 2008) failed to find an obvious association between bartonellosis and idiopathic rhinitis, in agreement with findings by Windsor et al. (2006).

#### **Clinical Features and Diagnosis**

The clinical features and diagnosis of idiopathic canine chronic rhinitis are similar to those described for idiopathic feline chronic rhinosinusitis. Chronic mucoid or mucopurulent nasal discharge is the most common clinical sign and is typically bilateral. Fresh blood may be seen in the discharge of some dogs, but it is not usually a primary complaint. Given that it is an idiopathic disease, the lack of specific findings is important. Dogs should have no funduscopic lesions, no lymphadenopathy, no facial or palate deformities, and healthy teeth and gums. Anorexia and weight loss are rarely reported. Thorough diagnostic testing is indicated, as described in Chapters 13 and 14. Results of such testing do not support the diagnosis of a specific disease. Usual nonspecific findings include turbinate erosion, mucosal inflammation, and increased mucus accumulation as assessed by nasal imaging and rhinoscopy; neutrophilic or mixed inflammation with bacteria on cytology of nasal discharge; and lymphoplasmacytic and/or neutrophilic inflammation on nasal biopsy. Nonspecific abnormalities attributable to chronic inflammation, such as epithelial hyperplasia and fibrosis, can also be seen. Secondary bacterial rhinitis or Mycoplasma infection may be identified.

#### **Treatment**

Treatment of idiopathic canine chronic rhinitis is also similar to that described for idiopathic feline rhinosinusitis. Dogs are treated for secondary bacterial rhinitis (as described on p. 233), and efforts are made to decrease irritants in the environment (see p. 233). As with cats, some dogs will benefit from efforts to facilitate the draining of nasal discharge by

humidification of air or instillation of sterile saline into the nasal cavity.

Burgener et al. (1987) reported successful treatment of dogs with lymphoplasmacytic rhinitis using immunosuppressive doses of prednisone (1 mg/kg q12h). A positive response is expected within 2 weeks, at which time the dose of prednisone is decreased gradually to the lowest effective amount. If no response to initial therapy occurs, other immunosuppressive drugs such as azathioprine can be added to the treatment regimen (see Chapter 103). Unfortunately, immunosuppressive treatment is not always effective. If clinical signs worsen during treatment with corticosteroids, the clinician should discontinue therapy and carefully reevaluate the dog for other diseases.

Other treatments that may be effective in some dogs include antihistamines or itraconazole. According to preliminary data from Kuehn (2006), administration of itraconazole (5 mg/kg q12h) resulted in dramatic improvement in clinical signs in some dogs with idiopathic chronic rhinitis. Treatment was required for a minimum of 3 to 6 months. The rationale for this treatment may be supported by the findings of increased fungal load in affected dogs by Windsor et al. (2006).

Dogs with severe or nonresponsive signs are candidates for rhinotomy and turbinectomy, as described for cats on p. 234.

#### **Prognosis**

The prognosis for idiopathic chronic rhinitis in dogs is generally good with respect to management of signs and quality of life. However, some degree of clinical signs persists in many dogs.

IN DOGS AND CATS

DIFFERENTIAL DIAGNOSES FOR PHARYNGEAL
SIGNS IN DOGS AND CATS

#### **CLINICAL SIGNS**

#### **LARYNX**

Regardless of the cause, diseases of the larynx result in similar clinical signs, most notably respiratory distress and stridor. Voice change is specific for laryngeal disease but is not always reported. Clients may volunteer that they have noticed a change in their dog's bark or cat's meow, but specific questioning may be necessary to obtain this important information. Localization of disease to the larynx can generally be achieved with a good history and physical examination. A definitive diagnosis is made through a combination of laryngeal radiography, laryngoscopy, and laryngeal biopsy.

Respiratory distress resulting from laryngeal disease is due to airway obstruction. Although most laryngeal diseases are progressive over several weeks to months, animals typically present in acute distress. Dogs and cats are able to compensate for their disease initially through self-imposed exercise restriction. Often an exacerbating event occurs, such as exercise, excitement, or high ambient temperature, resulting in markedly increased respiratory efforts. These increased efforts lead to excess negative pressures on the diseased larynx, sucking the surrounding soft tissues into the lumen, and causing laryngeal inflammation and edema. Obstruction to airflow becomes more severe, leading to even greater respiratory efforts (Fig. 16-1). The airway obstruction can ultimately be fatal.

A characteristic breathing pattern can often be identified on physical examination of patients in distress from extrathoracic (upper) airway obstruction, such as results from laryngeal disease (see Chapter 26). The respiratory rate is normal to only slightly elevated (often 30 to 40 breaths/min), which is particularly remarkable in the presence of overt distress. Inspiratory efforts are prolonged and labored, relative to expiratory efforts. The larynx tends to be sucked into the airway lumen as a result of negative pressure within the extrathoracic airways that occurs during inspiration, making inhalation of air more difficult. During expiration, pressures are positive in the extrathoracic airways, "pushing" the soft tissues open. Nevertheless, expiration may not be effortless. Some obstruction to airflow may occur during expiration with fixed obstructions, such as laryngeal masses. Even with the dynamic obstruction that results from laryngeal paralysis, in which expiration should be possible without any blockage to flow, resultant laryngeal edema and inflammation can interfere with normal expiration. On auscultation, referred upper airway sounds are heard and lung sounds are normal to increased.

Stridor, a high-pitched wheezing sound, is sometimes heard during inspiration. It is audible without a stethoscope, although auscultation of the neck may aid in identifying mild disease. Stridor is produced by air turbulence through the narrowed laryngeal opening. Narrowing of the extrathoracic trachea less commonly produces stridor.

In patients that are not presented for respiratory distress (e.g., for patients with exercise intolerance or voice change), it may be necessary to exercise the patient to identify the characteristic breathing pattern and stridor associated with laryngeal disease.

Some patients with laryngeal disease, particularly whose laryngeal paralysis is an early manifestation of diffuse neuromuscular disease or with distortion of normal laryngeal anatomy, have subclinical aspiration or overt aspiration pneumonia resulting from the loss of normal protective mechanisms. Patients may have clinical signs reflecting aspiration, such as cough, lethargy, anorexia, fever, tachypnea, and abnormal lung sounds. (See p. 309 for a discussion of aspiration pneumonia.)

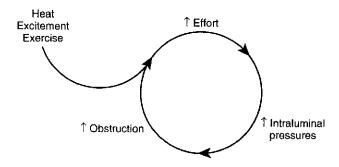

FIG 16-3
Patients with extrathoracic (upper) airway obstruction often present in respiratory distress as a result of a progressive worsening of airway obstruction after an exacerbating

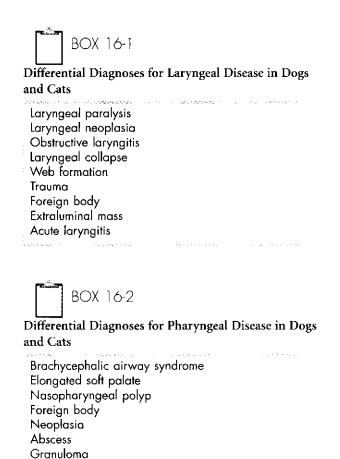

#### **PHARYNX**

Space-occupying lesions of the pharynx can cause signs of upper airway obstruction as described for the larynx, but overt respiratory distress occurs only with advanced disease. More typical presenting signs of pharyngeal disease are stertor, reverse sneezing, gagging, retching, and dysphagia. Stertor is a loud, coarse sound such as that produced by snoring or snorting. Stertor results from excessive soft tissue in the pharynx, such as an elongated soft palate or mass, causing turbulent air flow. Reverse sneezing (see p. 210), gagging, or retching may occur from local stimulation from the tissue itself or from secondary secretions. Dysphagia results from physical obstruction, usually because of a mass. As with laryngeal disorders, a definitive diagnosis is made through a combination of visual examination, radiography, and biopsy of abnormal tissue. Visual examination includes a thorough evaluation of the oral cavity, larynx (see p. 239), and caudal nasopharynx (see p. 215).

# DIFFERENTIAL DIAGNOSES FOR LARYNGEAL SIGNS IN DOGS AND CATS

Differential considerations for dogs and cats with respiratory distress are discussed in Chapter 26.

Dogs are more commonly presented for laryngeal disease than cats and usually have laryngeal paralysis (Box 16-1). Laryngeal neoplasia can occur in dogs or cats. Obstructive laryngitis is a poorly characterized inflammatory disorder. Other possible diseases of the larynx include laryngeal collapse (see p. 241), web formation (i.e., adhesions or fibrotic tissue across the laryngeal opening, usually as a complication of surgery), trauma, foreign body, and compression caused by an extraluminal mass. Acute laryngitis is not a well-characterized disease in dogs or cats but presumably could result from viral or other infectious agents, foreign bodies, or excessive barking.

# DIFFERENTIAL DIAGNOSES FOR PHARYNGEAL SIGNS IN DOGS AND CATS

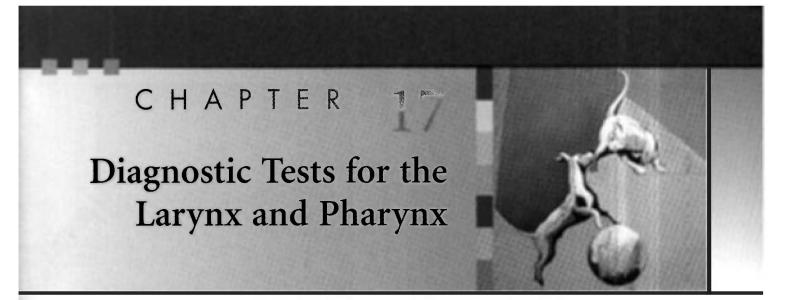

The most common pharyngeal disorders in dogs are brachycephalic airway syndrome and elongated soft palate (Box 16-2). Elongated soft palate is a component of brachycephalic airway syndrome and is discussed with this disorder in Chapter 18 (p. 244), but it can also occur in nonbrachycephalic dogs. The most common pharyngeal disorders in cats are lymphoma and nasopharyngeal polyps (Allen et al., 1999). Nasopharyngeal polyps, nasal tumors, and foreign bodies are discussed in the chapters on nasal diseases (see Chapters 13 to 15). Other differential diagnoses are abscess or granuloma and compression caused by an extraluminal mass.

#### CHAPTER OUTLINE

RADIOGRAPHY AND ULTRASONOGRAPHY LARYNGOSCOPY AND PHARYNGOSCOPY

# RADIOGRAPHY AND ULTRASONOGRAPHY

Radiographs of the pharynx and larynx should be evaluated in animals with suspected upper airway disease (Figs. 17-1 and 17-2). They are particularly useful in identifying radiodense foreign bodies such as needles, which can be embedded in tissues and may be difficult to find during laryngoscopy, and adjacent bony changes. Soft tissue masses and soft palate abnormalities may be seen, but apparent abnormal opacities are often misleading, particularly if there is any rotation of the head and neck, and overt abnormalities are often not identified. Abnormal soft tissue opacities or narrowing of the airway lumen identified radiographically must be confirmed withlaryngoscopy or endoscopy and biopsy. Laryngeal paralysis cannot be detected radiographically.

A lateral view of the larynx, caudal nasopharynx, and cranial cervical trachea is usually obtained. The vertebral column interferes with airway evaluation on dorsoventral or ventrodorsal (VD) projections. In animals with abnormal opacities identified on the lateral view, a VD or oblique view may confirm the existence of the abnormality and allow further localization of it. When radiographs of the laryngeal area are obtained, the head is held with the neck slightly extended. Padding under the neck and around the head may be needed to avoid rotation. Radiodense foreign bodies are readily identified. Soft tissue masses that are within the airway or that distort the airway are apparent in some animals with neoplasia, granulomas, abscesses, or polyps, and elongated soft palate is sometimes detectable.

Ultrasonography provides another noninvasive imaging modality for evaluating the pharynx and larynx, and laryngeal motion can be assessed. Because air interferes with sound waves, accurate assessment of this area can be difficult. Nevertheless, ultrasonography was found to be useful in the diagnosis of laryngeal paralysis in dogs (Rudorf et al., 2001). Localization of mass lesions and guidance of needle aspiration can also be performed.

Computed tomography or magnetic resonance imaging can be performed in patients with mass lesions to better determine extent of disease.

# LARYNGOSCOPY AND PHARYNGOSCOPY

Laryngoscopy and pharyngoscopy allow visualization of the larynx and pharynx for assessment of structural abnormalities and laryngeal function. The procedures are indicated in any dog or cat with clinical signs that suggest upper airway obstruction or laryngeal or pharyngeal disease. It should be noted that patients with increased respiratory efforts resulting from upper airway obstruction might have difficulty during recovery from anesthesia. For a period of time between removal of the endotracheal tube and full recovery of neuromuscular function, the patient may be unable to maintain an open airway. Therefore laryngoscopy should not be undertaken in these patients unless the clinician is prepared to perform whatever surgical treatments may be indicated during the same anesthetic period.

The animal is placed in sternal recumbency. Anesthesia is induced and maintained with a short-acting injectable agent without prior sedation. Propofol, sodium thiopental, or sodium thiamylal is commonly used. Depth of anesthesia is carefully titrated, with just enough drug administered to allow visualization of the laryngeal cartilages; some jaw tone is maintained, and spontaneous deep respirations occur. Gauze is passed under the maxilla behind the canine teeth, and the head is elevated by hand or by tying the gauze to a stand (Fig. 17-3). This positioning avoids external compression of the neck. Retraction of the tongue with a gauze sponge should allow visualization of the caudal pharynx and larynx. A laryngoscope is also helpful in illuminating this region and enhancing visualization.

FIG 17-1

Lateral radiograph of the neck, larynx, and pharynx showing normal anatomy. Note that the patient's head and neck are not rotated. Excellent visualization of the soft palate and epiglottis are possible. Images obtained from poorly positioned patients often result in the appearance of "lesions" such as masses or abnormal soft palate because normal structures are captured at an oblique angle or are superimposed on one another.

FIG 17-2 Lateral radiograph of a dog with a neck mass showing marked displacement of the larynx.

The motion of the arytenoid cartilages is evaluated while the patient takes several deep breaths. An assistant is needed to verbally report the onset of each inspiration and expiration by observing chest wall movements. Normally the arytenoid cartilages abduct symmetrically and widely with each

FIG 17-3

Dog positioned with the head held off the table by gauze passed around the maxilla and hung from an intravenous pole. The tongue is pulled out, and a laryngoscope is used to visualize the pharyngeal anatomy and laryngeal motion.

inspiration and close on expiration (Fig. 17-4). Laryngeal paralysis resulting in clinical signs is usually bilateral. The cartilages are not abducted during inspiration. In fact, they may be passively forced outward during expiration and/or sucked inward during inspiration, resulting in paradoxical motion.

If the patient fails to take deep breaths, doxapram hydrochloride (1.1-2.2 mg/kg, administered intravenously) can be given to stimulate breathing. In a study by Tobias et al. (2004), none of the potential systemic side effects of the drug were noted, but some dogs required intubation when increased breathing efforts resulted in significant obstruction to airflow at the larynx.

If no laryngeal motion is observed, examination of the arytenoid cartilages should be continued as long as possible while the animal recovers from anesthesia. Effects of anesthesia and shallow breathing are the most common causes for an erroneous diagnosis of laryngeal paralysis.

After evaluation of laryngeal function, the plane of anesthesia is deepened and the caudal pharynx and larynx are thoroughly evaluated for structural abnormalities, foreign bodies, or mass lesions; appropriate diagnostic samples should be obtained for histopathologic analysis and perhaps culture. The length of the soft palate should be assessed. The soft palate normally extends to the tip of the epiglottis during inhalation. An elongated soft palate can contribute to signs of upper airway obstruction.

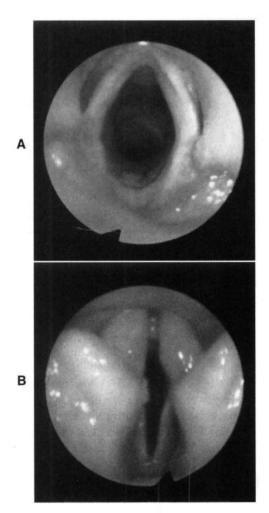

FIG 17-4
Canine larynx. A, During inspiration, arytenoid cartilages and vocal folds are abducted, resulting in wide symmetric opening to trachea. B, During expiration, cartilages and vocal folds nearly close the glottis.

As described in Chapter 14, the caudal nasopharynx should be evaluated for nasopharyngeal polyps, mass lesions, and foreign bodies. Needles or other sharp objects may be buried in tissue, and careful visual examination and palpation are required for detection.

Neoplasia, granulomas, abscesses, or other masses can occur within or external to the larynx or pharynx, causing compression or deviation of normal structures or both. Severe, diffuse thickening of the laryngeal mucosa can be caused by infiltrative neoplasia or obstructive laryngitis. Biopsy specimens for histologic examination should be obtained from any lesions to establish an accurate diagnosis because the prognoses for these diseases are quite different. The normal diverse flora of the pharynx makes culture results difficult or impossible to interpret. Bacterial growth from abscess fluid or tissue obtained from granulomatous lesions may represent infection.

Obliteration of most of the airway lumen by surrounding mucosa is known as *laryngeal collapse*. With prolonged upper airway obstruction, the soft tissues are sucked into the lumen by the increased negative pressure created as the dog or cat struggles to get air into its lungs. Eversion of the laryngeal saccules, thickening and elongation of the soft palate, and inflammation with thickening of the pharyngeal mucosa can occur. The laryngeal cartilages can become soft and deformed, unable to support the soft tissues of the pharynx. It is unclear whether this chondromalacia is a concurrent or secondary component of laryngeal collapse. Collapse most often occurs in dogs with brachycephalic airway syndrome but can also occur with any chronic obstructive disorder.

The trachea should be examined radiographically or visually with an endoscope if abnormalities are not identified on laryngoscopy in the dog or cat with signs of upper airway obstruction. For these animals, the laryngeal cartilages can be held open with an endotracheal tube for a cursory examination of the proximal trachea at the time of laryngoscopy if an endoscope is not available.

# CHAPTER

# Disorders of the Larynx and Pharynx

#### CHAPTER OUTLINE

LARYNGEAL PARALYSIS
BRACHYCEPHALIC AIRWAY SYNDROME
OBSTRUCTIVE LARYNGITIS
LARYNGEAL NEOPLASIA

#### LARYNGEAL PARALYSIS

Laryngeal paralysis refers to a failure of the arytenoid cartilages to abduct during inspiration, creating extrathoracic (upper) airway obstruction. The abductor muscles are innervated by the left and right recurrent laryngeal nerves. If clinical signs develop, both arytenoid cartilages are usually affected.

#### Etiology

Potential causes of laryngeal paralysis are listed in Box 18-1. Laryngeal paralysis is most often idiopathic. Trauma or neoplasia involving the ventral neck can damage the recurrent laryngeal nerves directly or through inflammation and scarring. Masses or trauma involving the anterior thoracic cavity can also cause damage to the recurrent laryngeal nerves as they course around the subclavian artery (right side) or ligamentum arteriosum (left side). Dogs with polyneuropathy-polymyopathy can be presented with laryngeal paralysis as the predominant clinical sign. Polyneuropathies in turn have been associated with immune-mediated diseases, endocrinopathies, or other systemic disorders (see Chapter 71). Congenital laryngeal paralysis has been documented in the Bouvier des Flandres and is suspected in Siberian Huskies and Bull Terriers. A laryngeal paralysis-polyneuropathy complex has been described in young Dalmations, Rottweilers, and Great Pyrenees. Anecdotally, there may be an increasing incidence of idiopathic laryngeal paralysis in older Golden and Labrador Retrievers, and in one study 47 of 140 dogs (34%) with laryngeal paralysis were Labrador Retrievers (MacPhail et al., 2001). Laryngeal paralysis is uncommon in cats.

#### **Clinical Features**

Laryngeal paralysis can occur at any age and in any breed, although the idiopathic form is most commonly seen in older large-breed dogs. Clinical signs of respiratory distress and stridor are a direct result of narrowing of the airway at the arytenoid cartilages and vocal folds. The owner may also note a change in voice (i.e., bark or meow). Most patients are presented for acute respiratory distress, in spite of the chronic, progressive nature of this disease. Decompensation is frequently a result of exercise, excitement, or high environmental temperatures, resulting in a cycle of increased respi-

ratory efforts; increased negative airway pressures, which suck the soft tissue into the airway; and pharyngeal edema and inflammation, which lead to further increased respiratory efforts. Cyanosis, syncope, and death can occur. Dogs with respiratory distress require immediate emergency therapy.

Some dogs with laryngeal paralysis exhibit gagging or coughing with eating or have overt aspiration pneumonia, presumably resulting from concurrent pharyngeal dysfunction or a more generalized polyneuropathy-polymyopathy.

#### Diagnosis

A definitive diagnosis of laryngeal paralysis is made through laryngoscopy (see p. 239). Movement of the arytenoid cartilages is observed during a light plane of anesthesia while the patient is taking deep breaths. In laryngeal paralysis the arytenoid cartilages and vocal folds remain closed during inspiration and open slightly during expiration. The larynx does not exhibit the normal coordinated movement associated with breathing, opening on inspiration and closing on expiration. Additional laryngoscopic findings may include pharyngeal edema and inflammation. The larynx and pharynx are also examined for neoplasia, foreign bodies, or other diseases that might interfere with normal function and for laryngeal collapse (see p. 241).

Once a diagnosis of laryngeal paralysis is established, additional diagnostic tests should be considered to identify underlying or associated diseases, to rule out concurrent pulmonary problems (e.g., aspiration pneumonia) that may be contributing to the clinical signs, and to rule out concurrent pharyngeal and esophageal motility problems (Box 18-2). The latter is especially important if surgical correction for the treatment of laryngeal paralysis is being considered. If the diagnostic tests fail to identify a cause, idiopathic laryngeal paralysis is diagnosed.

#### **Treatment**

In animals with respiratory distress, emergency medical therapy to relieve upper airway obstruction is indicated (see Chapter 26). Following stabilization and a thorough diagnostic evaluation, surgery is usually the treatment of choice. Even when specific therapy can be directed at an associated disease (e.g., hypothyroidism), complete resolution of clinical signs of laryngeal paralysis is rarely seen. Also, most cases are idiopathic, and signs are generally progressive.

Various laryngoplasty techniques have been described, including arytenoid lateralization (tie-back) procedures, partial laryngectomy, and castellated laryngoplasty. The goal of surgery is to provide an adequate opening for the flow of air but not one so large that the animal is predisposed to aspiration and the development of pneumonia. Several operations to gradually enlarge the glottis may be necessary to minimize the chance of subsequent aspiration. The recommended initial procedure for most dogs and cats is unilateral arytenoid lateralization.

If surgery is not an option, medical management consisting of antiinflammatory doses of short-acting glucocorti-

coids (e.g., prednisone, 0.5 mg/kg given orally q12h initially) and cage rest may reduce secondary inflammation and edema of the pharynx and larynx and enhance airflow.

#### **Prognosis**

The overall prognosis for dogs with laryngeal paralysis treated surgically is fair to good. As many as 90% of owners of dogs with laryngeal paralysis that underwent unilateral arytenoid lateralization consider the procedure successful I year or longer after surgery (White, 1989; Hammel et al., 2006). MacPhail et al. (2001) reported a median survival time of 1800 days (nearly 5 years) for 140 dogs that underwent various surgical procedures, although the mortality rate from postoperative complications was high at 14%. The most common complication is aspiration pneumonia. A guarded prognosis is warranted for patients with signs of aspiration, dysphagia, megaesophagus, or systemic polyneuropathy or polymyopathy. Dogs with laryngeal paralysis as an early manifestation of generalized polyneuropathy or polymyopathy may have progression of signs.

#### BRACHYCEPHALIC AIRWAY SYNDROME

The term brachycephalic airway syndrome, or upper airway obstruction syndrome, refers to the multiple anatomic abnor-

В

FIG 18-1
Two Bulldog puppies (A) and a Boston Terrier (B) with brachycephalic airway syndrome. Abnormalities can include stenotic nares, elongated soft palate, everted laryngeal saccules, laryngeal collapse, and hypoplastic trachea.

malities commonly found in brachycephalic dogs and, to a lesser extent, in short-faced cats such as Himalayans. The predominant anatomic abnormalities include stenotic nares, elongated soft palate, and, in Bulldogs, hypoplastic trachea. Prolonged upper airway obstruction resulting in increased inspiratory efforts may lead to eversion of the laryngeal saccules and, ultimately, laryngeal collapse. The severity of these abnormalities varies, and one or any combination of these abnormalities may be present in any given brachycephalic dog or short-faced cat (Fig. 18-1).

Concurrent gastrointestinal signs such as ptyalism, regurgitation, and vomiting are common in dogs with brachycephalic airway syndrome (Poncet et al., 2005) Underlying gastrointestinal disease may be a concurrent problem in these breeds of dogs or may result from or be exacerbated by the increased intrathoracic pressures generated in response to the upper airway obstruction.

#### **Clinical Features**

The abnormalities associated with the brachycephalic airway syndrome impair the flow of air through the extrathoracic (upper) airways and cause clinical signs of upper airway obstruction, including loud breathing sounds, stertor, increased inspiratory efforts, cyanosis, and syncope. Clinical signs are exacerbated by exercise, excitement, and high environmental temperatures. The increased inspiratory effort commonly associated with this syndrome may cause secondary edema and inflammation of the laryngeal and pharyngeal mucosae and enhance eversion of the laryngeal saccules or laryngeal collapse, further narrowing the glottis, exacerbating the clinical signs, and creating a vicious cycle. As a result, some dogs may be presented with life-threatening upper airway obstruction that requires immediate emergency therapy. Concurrent gastrointestinal signs are commonly reported.

#### **Diagnosis**

A tentative diagnosis is made on the basis of the breed, clinical signs, and the appearance of the external nares (Fig. 18-2). Stenotic nares are generally bilaterally symmetric, and the alar folds may be sucked inward during inspiration, thereby worsening the obstruction to airflow. Laryngoscopy (see Chapter 17) and radiographic evaluation of the trachea (see Chapter 20) are necessary to fully assess the extent and severity of abnormalities. Most other causes of upper airway obstruction (see Chapter 26, and Boxes 16-1 and 16-2) can also be ruled in or out on the basis of the results of these diagnostic tests.

#### **Treatment**

Therapy should be designed to enhance the passage of air through the upper airways and to minimize the factors that exacerbate the clinical signs (e.g., excessive exercise and excitement, overheating). Surgical correction of the anatomic defects is the treatment of choice. The specific surgical procedure selected depends on the nature of the existing problems and can include widening of the external nares and removal of excessive soft palate and everted laryngeal saccules.

Correction of stenotic nares is a simple procedure and can lead to a surprising alleviation of the signs in affected patients. Stenotic nares can be safely corrected at 3 to 4 months of age, *ideally before clinical signs develop*. The soft palate should be evaluated at the same time and also corrected if elongated. Such early relief of obstruction should decrease the amount of negative pressure placed on the pharyngeal and laryngeal structures during inspiration and decrease progression of disease.

Medical management consisting of the administration of short-acting glucocorticoids (e.g., prednisone, 0.5 mg/kg given orally q12h initially) and cage rest may reduce the secondary inflammation and edema of the pharynx and larynx and enhance airflow, but it will not eliminate the problem. Emergency therapy may be required to alleviate the upper airway obstruction in animals presenting in respiratory distress (see Chapter 26).

Weight management and concurrent treatment for gastrointestinal disease should not be neglected in patients with brachycephalic airway syndrome.

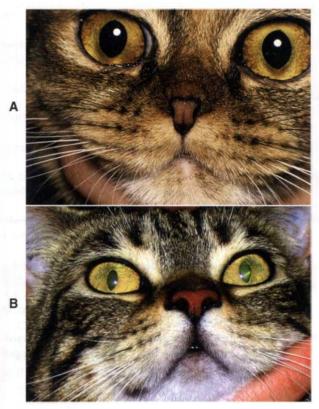

FIG 18-2
Cat with severely stenotic nares (A), as compared with the nares of a normal cat (B). Early correction of stenotic nares and other amenable upper airway obstructions, such as an elongated soft palate, is highly recommended.

#### **Prognosis**

The prognosis depends on the severity of the abnormalities at the time of diagnosis and the ability to surgically correct them. The clinical signs will progressively worsen if the underlying problems go uncorrected. The prognosis after early surgical correction of the abnormalities is good for many animals. Laryngeal collapse (see p. 241) is generally considered a poor prognostic indicator, although a recent study demonstrated that even dogs with severe laryngeal collapse can respond well to surgical intervention (Torrez et al., 2006). Permanent tracheostomy can be considered as a salvage procedure in animals with severe collapse that are not responsive. A hypoplastic trachea is not surgically correctable, but there is no clear relationship between the degree of hypoplasia and morbidity or mortality.

#### **OBSTRUCTIVE LARYNGITIS**

Nonneoplastic infiltration of the larynx with inflammatory cells can occur in dogs and cats, causing irregular proliferation, hyperemia, and swelling of the larynx. Clinical signs of an upper airway obstruction result. The larynx may appear grossly neoplastic during laryngoscopy

but is differentiated from neoplasia on the basis of the histopathologic evaluation of biopsy specimens. Inflammatory infiltrates can be granulomatous, pyogranulomatous, or lymphocytic-plasmacytic. Etiologic agents have not been identified.

This syndrome is poorly characterized and probably includes several different diseases. Some animals respond to glucocorticoid therapy. Prednisone or prednisolone (1.0 mg/kg given orally q12h) is used initially. Once the clinical signs have resolved, the dose of prednisone can be tapered to the lowest amount that effectively maintains remission of clinical signs. Conservative excision of the tissue obstructing the airway may be necessary in animals with severe signs of upper airway obstruction or large granulomatous masses.

The prognosis varies, depending on the size of the lesion, the severity of laryngeal damage, and the responsiveness of the lesion to glucocorticoid therapy.

#### LARYNGEAL NEOPLASIA

Neoplasms originating from the larynx are uncommon in dogs and cats. More commonly, tumors originating in tissues adjacent to the larynx, such as thyroid carcinoma and lymphoma, compress or invade the larynx and distort normal laryngeal structures. Clinical signs of extrathoracic (upper) airway obstruction result. Laryngeal tumors include carcinoma (squamous cell, undifferentiated, and adenocarcinoma), lymphoma, melanoma, mast cell tumors and other sarcomas, and benign neoplasia. Lymphoma is the most common tumor in cats.

#### **Clinical Features**

The clinical signs of laryngeal neoplasia are similar to those of other laryngeal diseases and include noisy respiration, stridor, increased inspiratory efforts, cyanosis, syncope, and a change in bark or meow. Mass lesions can also cause concurrent dysphagia, aspiration pneumonia, or visible or palpable masses in the ventral neck.

#### **Diagnosis**

Extralaryngeal mass lesions are often identified by palpation of the neck. Primary laryngeal tumors are rarely palpable and are best identified by laryngoscopy. Laryngeal radiographs, ultrasonography, or computed tomography can be useful in assessing the extent of disease. Differential diagnoses include obstructive laryngitis, nasopharyngeal polyp, foreign body, traumatic granuloma, and abscess. For a definitive diagnosis of neoplasia to be made, histologic examination of a biopsy specimen of the mass must be done. A diagnosis of malignant neoplasia should not be made on the basis of the gross appearance alone.

#### **Treatment**

The therapy used depends on the type of tumor identified histologically. Benign tumors should be excised surgically, if possible. Complete surgical excision of malignant tumors is rarely possible, although ventilation may be improved and time may be gained to allow other treatments such as radiation or chemotherapy to become effective. Complete laryngectomy and permanent tracheostomy may be considered in select animals.

#### **Prognosis**

The prognosis in animals with benign tumors is excellent if the tumors can be totally resected. Malignant neoplasms are associated with a poor prognosis.

**CLINICAL SIGNS** 

Cough

Exercise Intolerance and Respiratory Distress
DIAGNOSTIC APPROACH TO DOGS AND CATS
WITH LOWER RESPIRATORY TRACT DISEASE

Initial Diagnostic Evaluation

Pulmonary Specimens and Specific Disease Testing

#### **CLINICAL SIGNS**

In this discussion, the term lower respiratory tract disorders refers to diseases of the trachea, bronchi, bronchioles, alveoli, interstitium, and vasculature of the lung (Box 19-1). Dogs and cats with diseases of the lower respiratory tract are commonly seen for evaluation of cough. Lower respiratory tract diseases that interfere with the oxygenation of blood can result in respiratory distress, exercise intolerance, weakness, cyanosis, or syncope. Nonlocalizing signs such as fever, anorexia, weight loss, and depression also occur and are the only presenting sign in some animals. In rare instances, potentially misleading signs, such as vomiting, can occur in animals with lower respiratory tract disease. Auscultation and thoracic radiography help localize the disease to the lower respiratory tract in these animals. The two major presenting signs in animals with lower respiratory tract disease, cough and respiratory distress, can be further characterized by a careful history and physical examination.

#### COUGH

A cough is an explosive release of air from the lungs through the mouth. It is generally a protective reflex to expel material from the airways, although inflammation or compression of the airways can also stimulate cough. Cough is sometimes caused by disease outside of the lower respiratory tract. Chylothorax can cause cough. Although not well documented in dogs or cats, gastroesophageal reflux and postnasal drip are common causes of cough in people.

Classically, differential diagnoses for cough are divided into those that cause productive cough and those that cause nonproductive cough. A productive cough results in the delivery of mucus, exudate, edema fluid, or blood from the airways into the oral cavity. A moist sound can often be heard during the cough. Animals rarely expectorate the fluid, but swallowing can be seen after a coughing episode. If expectoration occurs, clients may confuse the cough with vomiting. In human medicine, categorizing cough as productive or nonproductive is rarely difficult because the patient can report the coughing up of secretions. In veterinary medicine, recognition of a productive cough is more difficult. If the owner or veterinarian has heard or seen evidence that the cough is productive, it usually is. However, not hearing or seeing evidence of productivity does not rule out the possibility of its presence. Productive coughs are most commonly caused by inflammatory or infectious diseases of the airways or alveoli and by heart failure (Box 19-2).

Hemoptysis is the coughing up of blood. Blood-tinged saliva may be observed within the oral cavity or dripping from the commissures of the mouth after a cough. Hemoptysis is an unusual clinical sign that most commonly occurs in animals with heartworm disease or pulmonary neoplasia. Less common causes of hemoptysis are mycotic infections, foreign bodies, severe congestive heart failure, thromboembolic disease, lung lobe torsion, and some systemic bleeding disorders such as disseminated intravascular coagulation (see Box 19-2).

Intensity of cough is useful in prioritizing the differential diagnoses. Cough associated with airway inflammation (i.e., bronchitis) or large airway collapse is often loud, harsh, and paroxysmal. The cough associated with tracheal collapse is often described as a "goose-honk." Cough resulting from tracheal disease can usually be induced by palpation of the trachea, although the concurrent involvement of deeper airways is possible. Cough associated with pneumonias and pulmonary edema is usually soft.

The association of coughing with temporal events can be helpful. Cough resulting from tracheal disease is exacerbated by pressure on the neck, such as pulling on the animal's collar. Cough caused by heart failure tends to occur more

Differential Diagnoses for Lower Respiratory Tract Disease in Dogs and Cats

#### Disorders of the Trachea and Bronchi

Canine infectious tracheobronchitis Canine chronic bronchitis

Collapsing trachea

Feline bronchitis (idiopathic)

Allergic bronchitis

Bacterial and Mycoplasmal infections

Oslerus osleri infection

Neoplasia

  - Capillaria infection
  - Crenosoma infection

Aspiration pneumonia

Eosinophilic lung disease

Idiopathic interstitial pneumonias

Idiopathic pulmonary fibrosis

Pulmonary neoplasia

Pulmonary contusions

Pulmonary hypertension

Pulmonary thromboembolism

Pulmonary edema

frequently at night, whereas cough caused by airway inflammation (bronchitis) tends to occur more frequently upon rising from sleep or during and after exercise or exposure to cold air. The client's perception of frequency may be biased by the times of day during which they have the most contact with their pets, often in the evenings and during exercise.

Surprisingly, cats with many of the disorders listed in Box 19-2 do not cough. In cats that cough, the index of suspicion for bronchitis, lung parasites, and heartworm disease is high.

### EXERCISE INTOLERANCE AND RESPIRATORY DISTRESS

Diseases of the lower respiratory tract can compromise the lung's function of oxygenating the blood through a variety of mechanisms (see the section on blood gas analysis in Chapter 20). Clinical signs of such compromise begin as mildly increased respirations and subtly decreased activity and progress through exercise intolerance (manifested as reluctance to exercise or respiratory distress with exertion) to overt respiratory distress at rest. Because of compensatory mechanisms, the ability of most pets to self-regulate their activity, and the inability of pets to communicate, many veterinary patients with compromised lung function arrive in overt respiratory distress. Dogs in overt distress will often stand with their neck extended and elbows abducted. Movements of the abdominal muscles may be exaggerated. Healthy

cats have minimally visible respiratory efforts. Cats that show noticeable chest excursions or open-mouth breathing are severely compromised. Patients in overt distress require rapid physical assessment and immediate stabilization before further diagnostic testing, as discussed in Chapter 26.

#### Resting Respiratory Rate

Resting respiratory rate can be used as an indicator of pulmonary function in patients that are not yet in respiratory distress. The measurement is ideally made at home by the owner, which spares the patient the stress of the veterinary hospital. The normal respiratory rate of a dog or cat without stress, at rest, is less than 20 respirations per minute. A rate of up to 30 respirations per minute is generally considered normal during a routine physical examination.

#### **Mucous Membrane Color**

Cyanosis, in which normally pink mucous membranes are bluish, is a sign of severe hypoxemia and indicates that the increased respiratory effort is not sufficiently compensating for the degree of respiratory dysfunction. Pallor of mucous membranes is a more common sign of acute hypoxemia resulting from respiratory disease.

#### **Breathing Pattern**

Patients in respiratory distress resulting from diseases of the lower respiratory tract, excluding the large airways, typically

have rapid and often shallow respirations; increased expiratory or inspiratory efforts, or both; and abnormal lung sounds on auscultation. Patients with intrathoracic large airway obstruction (intrathoracic trachea and/or large bronchi) generally have normal to slightly increased respiratory rate; prolonged, labored expiration; and audible or auscultable expiratory sounds (see Chapter 26).

#### DIAGNOSTIC APPROACH TO DOGS AND CATS WITH LOWER RESPIRATORY TRACT DISEASE

#### INITIAL DIAGNOSTIC EVALUATION

The initial diagnostic evaluation of dogs or cats with signs of lower respiratory tract disease includes a complete history, physical examination, thoracic radiographs, and complete blood count (CBC). Further diagnostic tests are selected on the basis of information obtained from these procedures; these include the evaluation of specimens collected from the lower respiratory tract, tests for specific diseases, and arterial blood gas analysis. Historical information was discussed in previous paragraphs.

#### Physical Examination

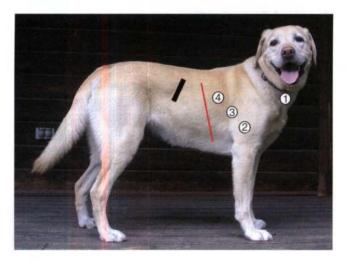

Measurement of respiratory rate, assessment of mucous membrane color, and observation of the breathing pattern were described in the previous sections. A complete physical examination, including a fundic examination, is warranted to identify signs of disease that may be concurrently or secondarily affecting the lungs (e.g., systemic mycoses, metastatic neoplasia, megaesophagus). The cardiovascular system should be carefully evaluated. Mitral insufficiency murmurs are frequently auscultated in older small-breed dogs brought to the clinician with the primary complaint of cough. Mitral insufficiency is often an incidental finding, but the clinician must consider both cardiac and respiratory tract diseases as differential diagnoses in these animals. Mitral insufficiency can lead to left atrial enlargement with compression of the mainstem bronchi, causing cough, or to congestive heart failure. Dogs in congestive heart failure are nearly always tachycardic, and any cough is usually soft. Other signs of heart disease include prolonged capillary refill time, weak or irregular pulses, abnormal jugular pulses, ascites or subcutaneous edema, gallop rhythms, and pulse deficits. Thoracic radiographs and occasionally echocardiography may be needed before cardiac problems can be comfortably ruled out as a cause of lower respiratory tract signs.

**Thoracic auscultation.** Careful auscultation of the upper airways and lungs is a critical component of the physical examination in dogs and cats with respiratory tract signs. Auscultation should be performed in a quiet location with the animal calm. Panting and purring do not result in deep inspiration, precluding evaluation of lung sounds. The heart and upper airways should be auscultated first. The clinician can then mentally subtract the contribution of these sounds from the sounds auscultated over the lung fields.

Initially, the stethoscope is placed over the trachea near the larynx (Fig. 19-1). Discontinuous snoring or snorting sounds can be referred from the nasal cavity and pharynx as a result of obstructions stemming from structural abnormalities, such as an elongated soft palate or mass lesions, and excessive mucus or exudate. Wheezes, which are continuous high-pitched sounds, occur in animals with obstructive laryngeal conditions, such as laryngeal paralysis, neoplasia, inflammation, and foreign bodies. Discontinuous snoring sounds and wheezes are known as stertor and stridor, respectively, when they can be heard without a stethoscope. The entire cervical trachea is then auscultated for areas of highpitched sounds caused by localized airway narrowing. Several breaths are auscultated with the stethoscope in each position, and the phase of respiration in which abnormal sounds occur is noted. Abnormal sounds resulting from extrathoracic disease are generally loudest during inspiration.

The lungs are auscultated next. Normally, the lungs extend cranially to the thoracic inlet and caudally to about the seventh rib ventrally along the sternum and to approximately the ninth intercostal space dorsally along the spine (see Fig. 19-1). The cranioventral, central, and dorsal lung fields on both the left and right sides are auscultated systematically.

<sup>\*</sup>Because it can be difficult to determine the productive nature of a cough in veterinary medicine, these differential diagnoses should also be considered in patients with nonproductive cough. †Diseases of the lower respiratory tract disease most often associated with cough in cats. Cough in cats is rarely identified as productive.

#### FIG 19-1

Auscultation of the respiratory tract begins with the stethoscope positioned over the trachea (stethoscope position 1). After assessing upper airway sounds, the stethoscope is positioned to evaluate the cranioventral, central, and dorsal lung fields on both sides of the chest (stethoscope positions 2), 3, and 4). Note that the lung fields extend from the thoracic inlet to approximately the seventh rib along the sternum and to approximately the ninth intercostal space along the spine (thin red line). Common mistakes are to neglect the cranioventral lung fields, reached by placing the stethoscope between the forelimb and the chest, and to position the stethoscope too far caudally, beyond the lung fields and over the liver. (Thick black line indicates position of the thirteenth rib.)

Any asymmetry in the sounds between the left and right sides is abnormal.

Normal lung sounds have been described historically as a mixture of "bronchial" and "vesicular" sounds, although all sounds originate from the large airways. The bronchial sounds are most prominent in the central regions of the lungs. They are tubular sounds similar in character to those heard over the trachea, but they are quieter. Vesicular sounds are most prominent in the peripheral lung fields. They are soft and have been likened to a breeze blowing through leaves. These normal sounds are best described as "normal breath sounds."

Decreased lung sounds over one or both sides of the thorax occur in dogs and cats with pleural effusion, pneumothorax, diaphragmatic hernia, or mass lesions. Surprisingly, consolidated lung lobes and mass lesions can result in enhanced lung sounds because of the improved transmission of airway sounds from adjacent lobes. Abnormal lungs sounds are described as increased breath sounds (alternatively, harsh lung sounds), crackles, or wheezes. Increased breath sounds are a nonspecific finding but are common in patients with pulmonary edema or pneumonia. Crackles are nonmusical, discontinuous noises that sound like paper being crumpled or bubbles popping. Diseases resulting in the formation of edema or an exudate within the airways (e.g., pulmonary edema, infectious or aspiration pneumo-

nia, bronchitis) and some interstitial pneumonias, particularly interstitial fibrosis, can result in crackles. Wheezes are musical, continuous sounds that indicate the presence of airway narrowing. Narrowing can occur as a result of bronchoconstriction, bronchial wall thickening, exudate or fluid within the bronchial lumen, intraluminal masses, or external airway compression. They are most commonly heard in cats with bronchitis. Wheezes caused by an intrathoracic airway obstruction are loudest during early expiration. Sudden snapping at the end of expiration can be heard in some dogs with intrathoracic tracheal collapse.

#### Radiography

Thoracic radiographs are indicated in dogs and cats with lower respiratory tract signs. Neck radiographs should also be obtained in animals with suspected tracheal disease. Radiography is perhaps the single most helpful diagnostic tool in the evaluation of dogs and cats with intrathoracic disease. It helps in localizing the problem to an organ system (i.e., cardiac, pulmonary, mediastinal, pleural), identifying the area of involvement within the lower respiratory tract (i.e., vascular, bronchial, alveolar, interstitial), and narrowing the list of potential differential diagnoses. It also helps in the formulation of a diagnostic plan (see Chapter 20). Additional diagnostic tests are necessary in most animals to establish a definitive diagnosis.

#### **Complete Blood Count**

The CBC of patients with lower respiratory tract disease may show the anemia of inflammatory disease, polycythemia secondary to chronic hypoxia, or a white blood cell response characteristic of an inflammatory process of the lungs. The hematologic changes are insensitive, however, and an absence of abnormalities cannot be used as the basis for ruling out inflammatory lung diseases. For instance, only half of dogs with bacterial pneumonia have a neutrophilic leukocytosis and left shift. Abnormalities are also not specific. For instance, eosinophilia is commonly encountered as a result of hypersensitivity or parasitic disease involving organs other than the lung.

# PULMONARY SPECIMENS AND SPECIFIC DISEASE TESTING

Based on results of the history, physical examination, thoracic radiographs, and CBC, a prioritized list of differential diagnoses is developed. Additional diagnostic tests (Fig. 19-2) are nearly always required to achieve a definitive diagnosis, which is necessary for optimal therapy and outcome. Selection of appropriate tests is based on the most likely differential diagnoses, the localization of disease within the lower respiratory tract (e.g., diffuse bronchial disease, single mass lesion), the degree of respiratory compromise of the patient, and the client's motivation for optimal care.

Invasive and noninvasive tests are available. Noninvasive tests have the obvious advantage of being nearly risk free but are usually aimed at confirming a specific diagnosis. Most patients with lower respiratory tract disease require collec-

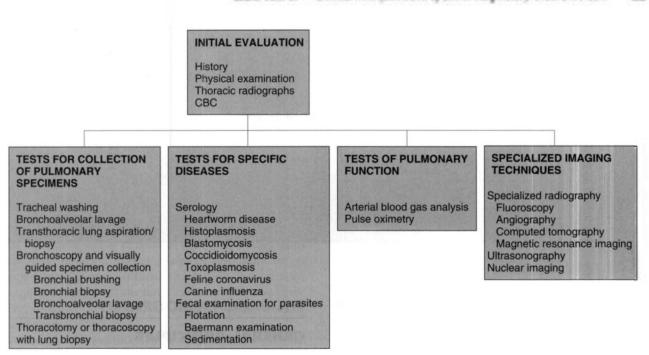

FIG 19-2
Diagnostic approach for dogs and cats with lower respiratory tract disease.

tion of a pulmonary specimen for microscopic and microbiologic analysis to further narrow the list of differential diagnoses or make a definitive diagnosis. Although the procedures for specimen collection from the lung are considered invasive, they carry varying degrees of risk, depending on the procedure used and the degree of respiratory compromise of the patient. The risk is minimal in many instances.

Noninvasive tests include serology for pulmonary pathogens, fecal examinations for parasites, and specialized imaging techniques such as fluoroscopy, angiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and nuclear imaging. Techniques for collection of pulmonary specimens that can be performed without specialized equipment include tracheal wash, bronchoalveolar lavage, and transthoracic lung aspiration. Visually guided specimens can be collected during bronchoscopy. Bronchoscopy has the additional benefit of allowing visual assessment of the airways. If analysis of lung specimens and results of reasonable noninvasive tests

do not provide a diagnosis in a patient with progressive disease, thoracoscopy or thoracotomy with lung biopsy is indicated.

Valuable information about patients with lower respiratory tract disease can also be obtained by assessing lung function through arterial blood gas analysis. Results are rarely helpful in making a final diagnosis, but they are useful in determining degree of compromise and in monitoring response to therapy. Pulse oximetry, a noninvasive technique to measure oxygen saturation of the blood, is particularly valuable in monitoring patients with respiratory compromise during anesthetic procedures or respiratory crises.

#### THORACIC RADIOGRAPHY

#### **GENERAL PRINCIPLES**

Thoracic radiographs play an integral role in the diagnostic evaluation of dogs and cats with clinical signs related to the lower respiratory tract. They are also indicated for the evaluation of animals with vague, nonspecific signs of disease to detect occult pulmonary disease. Thoracic radiographs can be helpful in localizing disease processes, narrowing and prioritizing the differential diagnoses, determining the extent of disease involvement, and monitoring the progression of disease and response to treatment.

A minimum of two views of the thorax should be taken in all dogs and cats. Right lateral and ventrodorsal (VD) views usually are preferred. The sensitivity of radiographs in the detection of lesions is improved if both right and left lateral views are obtained. These are indicated if disease of the right middle lung lobe, metastatic disease, or other subtle changes are suspected. The side of the lung away from the table is more aerated, thereby providing more contrast for soft-tissue opacities, and is slightly magnified compared with the side against the table. Dorsoventral (DV) views are taken to evaluate the dorsal pulmonary arteries in animals with suspected heartworm disease, pulmonary thromboembolism, or pulmonary hypertension. The combination of DV and VD views has the same advantages as the combination of right and left lateral views in detecting subtle changes in the dorsally oriented vessels. DV, rather than VD, views are taken to minimize stress in animals in respiratory distress. Horizontal-beam lateral radiographs with the animal standing can be used to evaluate animals with suspected cavitary lesions or pleural effusion.

Careful technique is essential to ensure that thoracic radiographs are obtained that yield useful information. Poor technique can lead to either underinterpretation or overinterpretation of abnormalities. Appropriate film, settings, and development procedures should be used, and the films should be interpreted using proper lighting. The settings used are recorded so that the same technique can be used when obtaining future films, which allows for more critical

comparison of the progression of disease. The dog or cat should be restrained adequately to prevent movement, and a short exposure time is used.

Radiographs should be taken during maximum inspiration. Fully expanded lungs provide the most air contrast for soft-tissue opacities, and motion is also minimized during this phase of the respiratory cycle. Radiographic indications of maximum inspiration include widening of the angle between the diaphragm and vertebral column (representing maximal expansion of caudal lung lobes); a lucent region in front of the heart shadow (representing maximal expansion of the cranial lung lobes); flattening of the diaphragm; minimal contact between the heart and the diaphragm; and a well-delineated, nearly horizontal vena cava. Radiographs of the lungs obtained during phases of respiration other than peak inspiration are difficult to interpret. For example, incomplete expansion of the lungs can cause increased pulmonary opacities to be seen that appear pathologic, resulting in misdiagnosis.

Animals that are panting should be allowed to calm down before thoracic radiographs are obtained. A paper bag can be placed over the animal's muzzle to increase the concentration of carbon dioxide in the inspired air, causing the animal to take deeper breaths. It may be necessary to sedate some animals.

All structures of the thorax should be evaluated systematically in every animal to enhance diagnostic accuracy. Extrapulmonary abnormalities may develop secondary to pulmonary disease and may be the only radiographic finding (e.g., subcutaneous emphysema after tracheal laceration). Conversely, pulmonary disease may occur secondary to other evident thoracic diseases, such as mitral valve insufficiency, megaesophagus, and neoplasia of the body wall.

#### TRACHEA

The trachea and, in young animals, the thymus are recognizable in the cranial mediastinum. Radiographs of the cervical trachea must also be taken in dogs and cats with suspected upper airway obstruction or primary tracheal disease, most notably tracheal collapse. During evaluation of the trachea, it is important to obtain radiographs of the cervical portion during inspiration and of the thorax during both inspiration and expiration.

Only the inner wall of the trachea should be visible. If the outer wall of the trachea is identified, this is suggestive of pneumomediastinum. The trachea normally has a uniform diameter and is straight, deviating ventrally from the vertebral bodies on lateral views as it progresses toward the carina. It may appear elevated near the carina if the heart is enlarged or pleural effusion is present. Flexion or extension of the neck may cause bowing of the trachea. On VD views the trachea may deviate to the right of midline in some dogs. The tracheal cartilage becomes calcified in some older dogs and chondrodystrophic breeds.

The overall size and continuity of the tracheal lumen should also be evaluated. The normal tracheal lumen is nearly as wide as the laryngeal lumen. Hypoplastic tracheas

FIG 20-1 Lateral radiograph of a Bulldog with a hypoplastic trachea. The tracheal lumen (narrow arrows) is less than half the size of the larynx (broad arrows).

have a lumen less than half the normal size (Fig. 20-1). Strictures and fractured cartilage rings can cause an abrupt, localized narrowing of the air stripe. Mass lesions in the tissues adjacent to the trachea can compress the trachea, causing a more gradual, localized narrowing of the air stripe. In animals with extrathoracic tracheal collapse, the tracheal air stripe is narrowed in the cervical region during inspiration. In animals with intrathoracic tracheal collapse, the air stripe is narrowed on thoracic films during expiration. Fluoroscopy, available primarily through referral centers, provides a more sensitive assessment of tracheal collapse. Finally, the air contrast of the trachea sometimes allows foreign bodies or masses to be visualized within the trachea. Most foreign bodies lodge at the level of the carina or within the bronchi. The inability to radiographically identify a foreign body does not rule out the diagnosis, however.

#### LUNGS

The clinician must be careful not to overinterpret lung abnormalities on thoracic radiographs. A definitive diagnosis is not possible in most animals, and microscopic examination of pulmonary specimens, further evaluation of the heart, or testing for specific diseases is necessary. The lungs are examined for the possible presence of four major abnormal patterns: vascular, bronchial, alveolar, and interstitial. Mass lesions are considered with the interstitial patterns. Lung lobe consolidation, atelectasis, pulmonary cysts, and lung lobe torsions are other potential abnormalities. Animals with severe respiratory distress but normal thoracic radiograph findings usually have thromboembolic disease or have suffered a very recent insult to the lungs, such as trauma or aspiration (Box 20-1).

#### Vascular Pattern

The pulmonary vasculature is assessed by evaluating the vessels to the cranial lung lobes on the lateral view and the

\* Gastroesophageal reflux is a common cause of cough in people. Documentation in dogs and cats is limited, but the possibility should also be considered.

vessels to the caudal lung lobes on the VD or DV view. Normally, the blood vessels should taper gradually from the left atrium (pulmonary vein) or right ventricle (pulmonary arteries) toward the periphery of the lungs. Companion arteries and veins should be similar in size. Arteries and veins have a consistent relationship with each other and the associated bronchus. On lateral radiographs the pulmonary artery is dorsal and the pulmonary vein is ventral to the bronchus. On VD or DV radiographs the pulmonary artery is lateral and the pulmonary vein is medial to the bronchus. Vessels that are pointed directly toward or away from the X-ray beam are "end-on" and appear as circular nodules. They are distinguished from lesions by their association with a linear vessel and adjacent bronchus.

Abnormal vascular patterns generally involve an increase or decrease in the size of arteries or veins (Box 20-2). The finding of arteries larger than their companion veins indicates the presence of pulmonary hypertension or thromboembolism, most commonly caused by heartworm disease, a finding seen in both dogs and cats (Fig. 20-2). The pulmonary arteries often appear tortuous and truncated in such animals. Concurrent enlargement of the main pulmonary artery and right side of the heart may be seen in affected dogs. There may also be interstitial, bronchial, or alveolar infiltrates in cats and dogs with heartworm disease as a result of concurrent inflammation, edema, or hemorrhage.

Veins larger than their companion arteries indicate the presence of congestion resulting from left-sided heart failure. Pulmonary edema may also be present.

Dilation of both arteries and veins is an unusual finding, except in young animals. The finding of pulmonary over-circulation is suggestive of left-to-right cardiac or vascular shunts, such as patent ductus arteriosus and ventricular septal defects.

Pulmonic valve stenosis

Hyperinflation of the lungs Feline bronchitis (idiopathic)

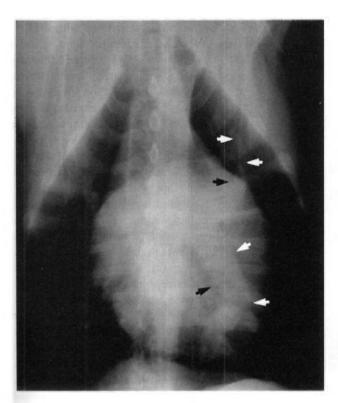

Allergic bronchitis

The finding of smaller-than-normal arteries and veins may indicate the presence of pulmonary undercirculation or hyperinflation. Undercirculation most often occurs in combination with microcardia resulting from hypoadreno-corticism or other causes of severe hypovolemia. Pulmonic stenosis may also cause radiographically visible undercirculation in some dogs. Hyperinflation is associated with obstructive airway disease, such as allergic or idiopathic feline bronchitis.

#### **Bronchial Pattern**

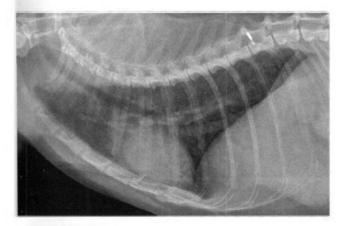

Bronchial walls are normally most easily discernible radiographically at the hilus. They should taper and grow thinner as they extend toward the periphery of each lung lobe. Bronchial structures are not normally visible radiographically in the peripheral regions of the lungs. The cartilage may be calcified in older dogs and chondrodystrophic breeds, making the walls more prominent but still sharply defined.

A bronchial pattern is caused by thickening of the bronchial walls or bronchial dilation. Thickened bronchial walls are visible as "tram lines" and "doughnuts" in the peripheral regions of the lung (Fig. 20-3). Tram lines are produced by airways that run transverse to the X-ray beam, causing the appearance of parallel thick lines with an air stripe in between. Doughnuts are produced by airways that are pointing directly toward or away from the beam, causing a thick

#### FIG 20-2

Dilation of pulmonary arteries is apparent on this ventrodorsal view of the thorax in a dog with heartworm disease. The artery to the left caudal lung lobe is extremely enlarged. *Arrowheads* delineate the borders of the arteries to the left cranial and caudal lobes.

#### FIG 20-3

A bronchointerstitial pattern is present in this lateral radiograph from a cat with idiopathic bronchitis. The bronchial component results from thickening of the bronchial walls and is characterized by "doughnuts" and "tram lines." In this radiograph the bronchial changes are most apparent in the caudal lung lobes.

circle to be seen radiographically, with the airway lumen creating the "hole." The walls of the bronchi tend to be indistinct. The finding of thickened walls indicates the presence of bronchitis and results from an accumulation of mucus or exudate along the walls within the lumens, an infiltration of

inflammatory cells within the walls, muscular hypertrophy, epithelial hyperplasia, or a combination of these changes. Potential causes of bronchial disease are listed in Box 20-3.

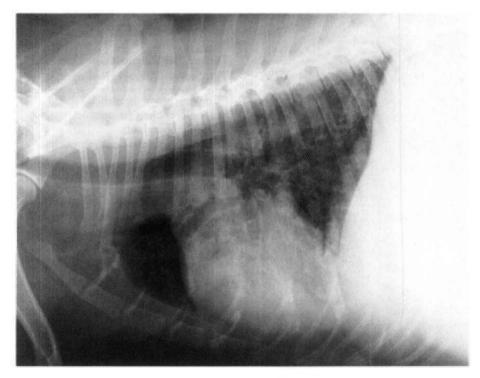

Chronic bronchial disease can result in irreversible dilation of the airways, which is termed *bronchiectasis*. It is identified radiographically by the presence of widened, nontapering airways (Fig. 20-4). Bronchiectasis can be cylindrical (tubular) or saccular (cystic). Cylindrical bronchiectasis is characterized by fairly uniform dilation of the airway. Saccular bronchiectasis additionally has localized dilations peripherally that can lead to a honeycomb appearance. All major bronchi are usually affected.

#### **Alveolar Pattern**

Alveoli are not normally visible radiographically. Alveolar patterns occur when the alveoli are filled with fluid-dense material (Box 20-4). The fluid opacity may be caused by edema, inflammation, hemorrhage, or neoplastic infiltrates, which generally originate from the interstitial tissues. The fluid-filled alveoli are silhouetted against the walls of the airways they surround. The result is a visible stripe of air from the airway lumen in the absence of definable airway walls. This stripe is an air bronchogram (Fig. 20-5). If the fluid continues to accumulate, the airway lumen will eventually also become filled with fluid, resulting in the formation of solid areas of fluid opacity, or consolidation.

Edema most often results from left-sided heart failure (see Chapter 22). In dogs the fluid initially accumulates in the perihilar region, and eventually the entire lung is affected. In cats patchy areas of edema can be present initially throughout the lung fields. The finding of enlarged pulmonary veins supports the cardiac origin of the infiltrates. Noncardiogenic edema is typically most severe in the caudal lung lobes.

Inflammatory infiltrates can be caused by infectious agents, noninfectious inflammatory disease, or neoplasia. The location of the infiltrative process can often help establish a tentative diagnosis. For example, diseases of airway origin, such as most bacterial and aspiration pneumonias, primarily affect the dependent lung lobes (i.e., the right middle and cranial lobes and the left cranial lobe). In con-

trast, diseases of vascular origin, such as dirofilariasis and thromboemboli, primarily affect the caudal lung lobes. Localized processes involving only one lung lobe suggest the presence of a foreign body, neoplasia, abscess, granuloma, or lung lobe torsion.

Hemorrhage usually results from trauma. Thromboembolism, neoplasia, coagulopathies, and fungal infections can also cause hemorrhage into the alveoli.

FIG 20-5

Lateral view of the thorax of a dog with aspiration pneumonia. An alveolar pattern is evident by the increased soft-tissue opacity with air bronchograms. Air bronchograms are bronchial air stripes without visible bronchial walls. In this radiograph the pattern is most severe in the ventral (dependent) regions of the lung, consistent with bacterial or aspiration pneumonia.

#### **Interstitial Pattern**

The pulmonary interstitial tissues confer a fine, lacy pattern to the pulmonary parenchyma of many dogs and cats as they age, in the absence of clinically apparent respiratory disease. They are not normally visible on inspiratory radiographs in young adult animals.

Abnormal interstitial patterns are reticular (unstructured), nodular, or reticulonodular in appearance. A nodular interstitial pattern is characterized by the finding of roughly circular, fluid-dense lesions in one or more lung lobes. However, the nodules must be nearly 1 cm in diameter to be routinely detected. Interstitial nodules may represent active or inactive inflammatory lesions or neoplasia (Box 20-5).

Active inflammatory nodules often have poorly defined borders. Mycotic infections typically result in the formation of multiple, diffuse nodules. The nodules may be small (miliary; Fig. 20-6) or large and coalescing. Parasitic granulomas are often multiple, although paragonimiasis can result in the formation of a single pulmonary nodule. Abscesses can form as a result of foreign bodies or as a sequela to bacterial pneumonia. Nodular patterns may also be seen on the radiographs obtained in animals with some eosinophilic lung diseases and idiopathic interstitial pneumonias.

Inflammatory nodules can persist as inactive lesions after the disease resolves. In contrast to active inflammatory nodules, however, the borders of inactive nodules are often well demarcated. Nodules may also become mineralized in some conditions, such as histoplasmosis. Well-defined, small, inactive nodules are sometimes seen in healthy older dogs without a history of disease. Radiographs taken several months later in these animals typically show no change in the size of these inactive lesions.

Neoplastic nodules may be singular or multiple (Fig. 20-7). They are often well defined, although secondary inflammation, edema, or hemorrhage can obscure the margins. There is no radiographic pattern that is diagnostic for neoplasia. Lesions caused by parasites, fungal infections,

and some eosinophilic lung diseases or idiopathic interstitial pneumonias may be indistinguishable from neoplastic lesions. In the absence of strong clinical evidence, malignant neoplasia must be confirmed cytologically or histologically. If this is not possible, radiographs can be obtained again 4 weeks later to evaluate for progression of disease.

Neoplastic involvement of the pulmonary parenchyma cannot be totally excluded on the basis of thoracic radiograph findings because malignant cells are present for a while before lesions reach a radiographically detectable size. The sensitivity of radiography in identifying neoplastic nodules can be improved by obtaining left and right lateral views of the thorax.

The reticular interstitial pattern is characterized by a diffuse, unstructured, lacy increase in the opacity of the pulmonary interstitium, which partially obscures normal

FIG 20-6

Lateral view of the thorax in a dog with blastomycosis. A miliary, nodular interstitial pattern is present. Increased soft-tissue opacity above the base of heart may be the result of hilar lymphadenopathy.

vascular and airway markings. Reticular interstitial patterns frequently occur in conjunction with nodular interstitial patterns (also called *reticulonodular patterns*) and alveolar and bronchial patterns (Fig. 20-8).

The increased reticular interstitial opacity can result from edema, hemorrhage, inflammatory cells, neoplastic cells, or fibrosis within the interstitium (Box 20-6). The interstitial space surrounds the airways and vessels and is normally extremely small in dogs and cats. With the continued accumulation of fluid or cells, however, the alveoli can become flooded, which produces an alveolar pattern. Visible focal interstitial accumulations of cells, or nodules, can also develop with time. Any of the diseases associated with alveolar and interstitial nodular patterns can cause a reticular interstitial pattern early in the course of disease (see Boxes 20-4 and 20-5). This pattern is also often seen in older dogs with no clinically apparent disease, presumably as a result of pulmonary fibrosis; this further decreases the specificity of the finding.

#### **Lung Lobe Consolidation**

Lung lobe consolidation is characterized by a lung lobe that is entirely soft-tissue opacity (Fig. 20-9, A). Consolidation occurs when an alveolar or interstitial disease process progresses to the point at which the entire lobe is filled with fluid or cells. Common differential diagnoses for lung lobe consolidation are severe bacterial or aspiration pneumonia (essentially resulting in an abscess of the entire lobe), neoplasia, lung lobe torsion, and hemorrhage. The inhalation of

plant material can also result in consolidation of the involved lung lobe as a result of the inflammatory reaction to the foreign material and secondary infection. This differential diagnosis should be considered especially in regions of the country where foxtails are prevalent.

Thoracic radiographs from three different patients, ventrodorsal projections. Radiograph A shows consolidation of the right middle lung lobe caused by neoplasia. Note that the soft tissue density of the lung silhouettes with the shadow of the heart. Radiograph B shows atelectasis of the middle region of the right lung and marked hyperinflation of the remaining lungs in a cat with idiopathic bronchitis. Note the shift of the heart shadow toward the collapsed region. Radiograph C shows atelectasis of the right middle lung lobe in another cat with idiopathic bronchitis. In this patient the adjacent lung lobes have expanded into the area previously occupied by the right middle lobe, preventing displacement of the

#### **Atelectasis**

Atelectasis is also characterized by a lobe that is entirely softtissue opacity. In this instance the lobe is collapsed as a result of airway obstruction. All the air within the lobe has been absorbed and not replaced. It is distinguished from consolidation by the small size of the lobe (Fig. 20-9, *B*). Often the heart is displaced toward the atelectatic lobe. Atelectasis is most commonly seen involving the right middle lobe of cats with bronchitis (Fig. 20-9, *C*). Displacement of the heart may not occur in these cats.

#### **Cavitary Lesions**

Cavity lesions describe any abnormal air accumulation in the lung. They can be congenital, acquired, or idiopathic. Specific types of cavitary lesions include bullae, which result from ruptured alveoli due to congenital weakness of tissues and/or small airway obstruction, such as in some cats with idiopathic bronchitis; blebs, which are bullae located within the pleura; and cysts, which are cavitary lesions lined by airway epithelium. Parasitic "cysts" (not lined by epithelium) can form around *Paragonimus* worms. Thoracic trauma is a common cause of cavitary lesions. Other differential diagnoses include neoplasia, lung infarction (from thromboembolism), abscess, and granuloma. Cavitary lesions may be apparent as localized accumulations of air or

fluid, often with a partially visible wall (Fig. 20-10). An airfluid interface may be visible using standing horizontal-beam projections. Bullae and blebs are rarely apparent radiographically.

Cavitary lesions may be discovered incidentally or on thoracic radiographs of dogs and cats with spontaneous pneumothorax. If pneumothorax is present, surgical excision of the lesion is usually indicated (see Chapter 25). If inflammatory or neoplastic disease is suspected, further diagnostic testing is indicated. If the lesion is found incidentally, animals can be periodically reevaluated radiographically to determine whether the lesion is progressing or resolving. If the lesion does not resolve during the course of 1 to 3 months, surgical removal is considered for diagnostic purposes and to prevent potentially life-threatening spontaneous pneumothorax.

#### **Lung Lobe Torsion**

Lung lobe torsion can develop spontaneously in deep-chested dogs or as a complication of pleural effusion or pneumonectomy in dogs and cats. The right middle and left cranial lobes are most commonly involved. The lobe usually twists at the hilus, obstructing the flow of blood into and out of the lung lobe. Venous drainage is obstructed before arterial flow, causing the lung lobe to become congested with blood. Over

**FIG 20-10**Ventrodorsal view of the thorax in a cat showing a cystic lesion (arrowheads) in the left caudal lung lobe. Differential diagnoses included neoplasia and *Paragonimus* infection.

time, air is absorbed from the alveoli and atelectasis can occur.

Lung lobe torsion is difficult to identify radiographically. Severe bacterial or aspiration pneumonia resulting in consolidation of these same lobes is far more common and produces similar radiographic changes. The finding of pulmonary vessels or bronchi traveling in an abnormal direction is strongly suggestive of torsion. Unfortunately, pleural fluid, if not present initially, often develops and obscures the radiographic image of the affected lobe. Ultrasonography is often useful in detecting a torsed lung lobe. Bronchoscopy, bronchography, computed tomography, or thoracotomy is necessary to confirm the diagnosis in some animals.

#### ANGIOGRAPHY

Angiography can be used to confirm a diagnosis of pulmonary thromboembolism. Obstructed arteries are blunted or do not show the normal gentle taper and arborization.

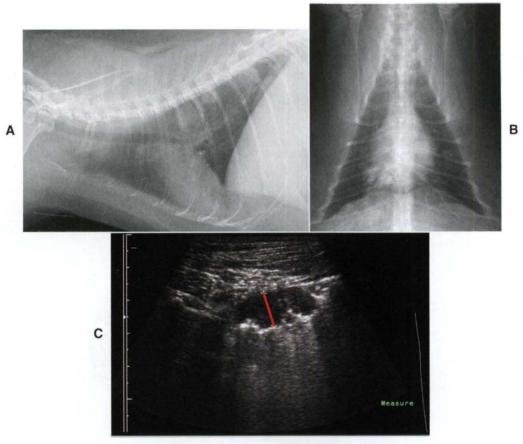

Arteries may appear dilated and tortuous. There also may be localized areas of extravasated contrast agent. If several days have elapsed since the embolization occurred, however, lesions may no longer be identifiable; therefore angiography should be performed as soon as the disorder is suspected and the animal's condition is stabilized. Angiography may also be used as a confirmatory test in cats with presumptive dirofilariasis but negative adult antigen blood test results and echocardiographic findings (see Chapter 10).

#### **ULTRASONOGRAPHY**

Ultrasonography is used to evaluate pulmonary mass lesions adjacent to the body wall, diaphragm, or heart and also consolidated lung lobes (Fig. 20-11). Because air interferes with the sound waves, aerated lungs and structures surrounded by aerated lungs cannot be examined. However, some patients with a reticular interstitial pattern on thoracic radiographs have sufficient infiltrates to be visualized where they abut the body wall. The consistency of lesions often can be determined to be solid, cystic, or fluid filled. Some solid masses are hypolucent and appear to be cystic on ultrasonograms. Vascular structures may be visible, particularly with Doppler ultrasound, and this can be helpful in identifying lung lobe torsion. Ultrasonography can also be used to guide needles or biopsy instruments into solid masses for specimen collection. It is used for evaluating the heart in animals with clinical signs that cannot be readily localized to either the cardiac or the respiratory systems. Ultrasonographic evaluation of patients with pleural disorders is discussed in Chapter 24.

# COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Computed tomography (CT) and magnetic resonance imaging (MRI) are used routinely in human medicine for the diagnostic evaluation of lung disease. The accessibility of CT in particular has led to its increased use in dogs and cats. The resultant three-dimensional images are more sensitive and specific for the identification of certain airway, vascular, and parenchymal diseases as compared with thoracic radiography. In a study of dogs with metastatic neoplasia, only 9% of nodules detected by CT were identified by thoracic radiography (Nemanic et al., 2006). Examples of cases that may benefit from CT include those with possible metastatic disease; possible pulmonary thromboembolism; idiopathic interstitial pneumonias, including idiopathic pulmonary fibrosis; or potentially excisable disease (to determine the extent and location of disease and the potential involvement of other structures, such as the major vessels). The application of CT and MRI to the diagnosis of specific canine and feline pulmonary diseases requires further investigation.

#### FIG 20-11

Multiple pulmonary nodules are easily visible on the lateral radiograph (A) from a cat with a one year history of cough and recent episodes of respiratory distress with wheezing. Nodules do not obviously extend to the chest wall based on the ventrodorsal radiograph (B). However, a 1-cm mass was found on ultrasonagraphic examination of the right thorax (C; a red line has been positioned between the ultrasound markers to indicate site of measurement). An ultrasound-guided aspirate was performed. The presence of eosinophils in the aspirate prompted the performance of fecal examinations for pulmonary parasites, and a diagnosis of paragonimiasis was made through the identification of characteristic ova.

#### **NUCLEAR IMAGING**

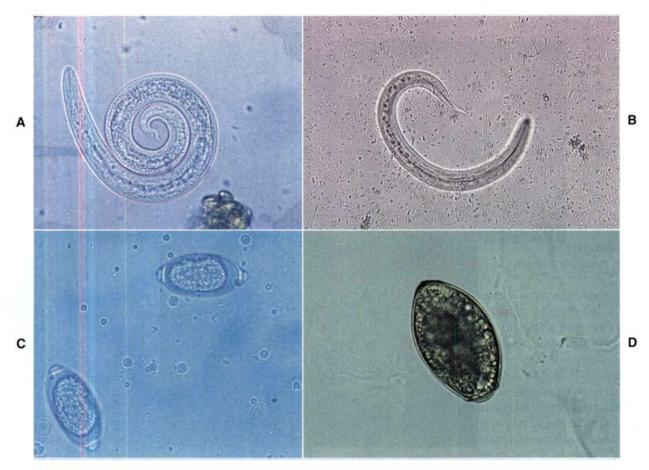

Mucociliary clearance can be measured by placing a drop of technetium-labeled albumin at the carina and observing its movement with a gamma camera to assist in the diagnosis of ciliary dyskinesia. Nuclear imaging can be used for the relatively noninvasive measurement of pulmonary perfusion and ventilation, valuable for the diagnosis of pulmonary thromboembolism. Restrictions for handling radioisotopes and the need for specialized recording equipment limit the availability of these tools to specialty centers.

#### **PARASITOLOGY**

Parasites involving the lower respiratory tract are identified by direct observation, blood tests, cytologic analysis of respiratory tract specimens, or fecal examinations. Oslerus osleri reside in nodules near the carina, which can be identified bronchoscopically. Rarely, other parasites may be seen. Blood tests are often used to diagnose heartworm disease (see Chapter 10).

Larvae that may be present in fluid from tracheal or bronchial washings include *O. osleri, Aelurostrongylus abstrusus* (Fig. 20-12, *A*), and *Crenosoma vulpis* (Fig. 20-12, *B*). Eggs that may be present include those of *Capillaria (Eucoleus) aerophila* and *Paragonimus kellicotti* (Fig. 20-12, *C* and *D*). Larvated eggs or larvae from *Filaroides hirthi* or *Aelurostrongylus milksi* can be present but are rarely associated with clinical signs. The more common organisms are described in Table 20-1.

The hosts of lung parasites generally cough up and swallow the eggs or larvae, which are then passed in the feces to infect the next host or an intermediate host. Fecal exami-

**FIG 20-12 A,** Larva of Aelurostrongylus abstrusus. **B,** Larva of Crenosoma vulpis. **C,** Double operculated ova of Capillaria sp. **D,** Single operculated ova of Paragonimus kellicotti.

nation for eggs or larvae is a simple, noninvasive tool for the diagnosis of such infestations. However, because shedding is intermittent, parasitic disease cannot be included solely on the basis of negative fecal examination findings. Multiple (at least three) examinations should be performed in animals that are highly suspected of having parasitic disease. If possible, several days should be allowed to elapse between each collection of feces.

Routine fecal flotation can be used to concentrate eggs from *C. aerophila*. High-density fecal flotation (specific gravity [s.g.], 1.30 to 1.35) can be used to concentrate *P. kellicotti* eggs. Sedimentation techniques are preferred for concentrating and identifying *P. kellicotti* eggs, particularly if few eggs are present. Larvae are identified through the use of the Baermann technique. However, *O. osleri* larvae are insufficiently motile for reliable identification with this technique, and zinc sulfate (s.g., 1.18) flotation is recommended. Even so, false-negative results are common in cases with *O. osleri*. All of these techniques can be readily performed at minimal expense. Methods for sedimentation and the Baermann technique are described in Boxes 20-7 and 20-8.

Toxoplasma gondii occasionally causes pneumonia in dogs and cats. Dogs do not shed Toxoplasma organisms in the feces, but cats may. However, the shedding of eggs is part of the direct life cycle of the organisms and does not correlate with the presence of systemic disease resulting from the indirect cycle. Infection is therefore diagnosed by finding tachyzoites in pulmonary specimens or indirectly on the basis of serologic findings.

Migrating intestinal parasites can cause transient pulmonary signs in young animals. Migration most often occurs before the mature adults develop in the intestine, and thus eggs may not be found in feces.

## **SEROLOGY**

Serologic tests can detect a variety of pulmonary pathogens. Antibody tests provide only indirect evidence of infection, however. In general, they should be used only to confirm a suspected diagnosis, not to screen for disease. Whenever possible, identification of the infectious organisms is the preferred method of diagnosis. Tests available for common

## TABLE 20-1

## Characteristics of Eggs or Larvae from Respiratory Parasites

PARASITE	HOST	STAGE	SOURCE	DESCRIPTION
Capillaria aerophila	Dog and cat	Eggs	Routine flotation of feces, airway specimens	Barrel shaped, yellow, with prominent, transparent, asymmetric bipolar plugs; slightly smaller than <i>Trichuris</i> eggs; 60-80 µm × 30-40 µm
Paragonimus kellicotti	Dog and cat	Eggs	High-density flotation or sedimentation of feces, airway specimens	Oval, golden-brown, single, operculated; operculum flat with prominent shoulders; 75-118 μm × 42-67 μm
Aelurostrongylus abstrusus	Cat	Larvae	Baermann technique of feces, airway specimens	Larvae with S-shaped tail; dorsal spine present; 350-400 μm × 17 μm; eggs or larvated eggs may be seen in airway specimens
Oslerus osleri	Dog	Larvae, eggs	Tracheal wash, bronchial brushing of nodules, zinc sulfate flotation of feces	Larvae have S-shaped tail without dorsal spine; rarely found eggs are thin-walled, colorless, and larvated; 80 × 50 μm
Crenosoma vulpis	Dog	Larvae	Baermann technique of feces, airway specimens	Larvae have tapered tail without severe kinks or spines; 250-300 μm; larvated eggs may be seen in airway specimens

## BOX 20-7

#### Sedimentation of Feces for Concentration of Eggs

- Homogenize 1 to 3 g of feces with water (at least 30 ml).
- Pass through coarse sieve or gauze (250-µm mesh), washing debris remaining in sieve with fine spray of water.
- 3. Pour filtrate into conical urine flask, and let stand for 2 minutes.
- 4. Discard most of supernate.
- 5. Pour remaining 12 to 15 ml into flat-bottomed tube, and let stand for 2 minutes.
- 6. Draw off supernate.
- 7. Add 2 to 3 drops of 5% methylene blue.
- 8. Examine under low power.

Data from Urquhart GM et al: *Veterinary parasitology,* ed 2, Oxford, 1996, Blackwell Science.

pulmonary pathogens include those for *Histoplasma*, *Blastomyces*, *Coccidiodomyces*, *Toxoplasma*, and feline coronavirus. These tests are discussed fully in Chapter 92. Antibody tests for canine influenza are discussed further in Chapter 22. Serum antigen tests for *Cryptococcus* (see Chapter 98) and adult heartworms are also available (see Chapter 10). Antibody tests for dirofilariasis are available and used primarily to support the diagnosis of feline heartworm disease (see Chapter 10).

## BOX 20-8

#### Baermann Technique for Concentration of Larvae

- 1. Set up apparatus.
  - a. Glass funnel supported in ring stand
  - b. Rubber tube attached to bottom of funnel, and closed with a clamp
  - c. Coarse sieve (250-µm mesh) placed in top of funnel
  - d. Double-layer gauze on top of sieve
- 2. Place feces on gauze in funnel.
- 3. Fill funnel slowly with water to immerse feces.
- 4. Leave overnight at room temperature.
- Collect water via rubber tube from neck of funnel in a Petri dish.
- 6. Examine under low power.

Data from Urquhart GM et al: *Veterinary parasitology,* ed 2, Oxford, 1996, Blackwell Science.

## TRACHEAL WASH

## **Indications and Complications**

Tracheal wash can yield valuable diagnostic information in animals with cough or respiratory distress resulting from disease of the airways or pulmonary parenchyma and in animals with vague presenting signs and pulmonary abnormalities detected on thoracic radiographs (i.e., most animals with lower respiratory tract disease). Tracheal wash is generally performed after results of the history, physical examination, thoracic radiography, and other routine components of the database are known.

Tracheal wash provides fluid and cells that can be used to identify discases involving the major airways while bypassing the normal flora and debris of the oral cavity and pharynx. The fluid obtained is evaluated cytologically and microbiologically and therefore should be collected before the initiation of antibiotic treatment whenever possible. Tracheal wash is likely to provide a representative specimen in patients with bronchial or alveolar disease (Table 20-2). It is less likely to identify interstitial and small focal disease processes. However, the procedure is inexpensive and minimally invasive, and this makes it reasonable to perform in most animals with lower respiratory tract disease if the risks of other methods of specimen collection are deemed too great. Potential complications are rare, and they include tracheal laceration, subcutaneous emphysema, and pneumomediastinum. Bronchospasm may be induced by the procedure in patients with hyperreactive airways, particularly cats with bronchitis.

## **TECHNIQUES**

Tracheal wash is performed using transtracheal or endotracheal techniques. Transtracheal wash is performed by passing a catheter into the trachea to the level of the carina through the cricothyroid ligament or between the tracheal rings in an awake or sedated animal. Endotracheal wash is performed by passing a catheter through an endotracheal tube in an anesthetized animal. The endotracheal technique is preferred in cats and very small dogs, although either technique can be used in any animal. Patients with airways that may be hyperreactive, particularly cats, are treated with bronchodilators (see the section on endotracheal technique).

## Transtracheal Technique

Transtracheal wash fluid is collected using an 18- to 22gauge through-the-needle intravenous catheter (e.g., Intracath; Becton, Dickinson and Company). The catheter should be long enough to reach the carina, which is located at approximately the level of the fourth intercostal space. The longest intravenous catheter available may be 12 inches (30 cm), which is long enough to reach from the cricothyroid ligament to the carina in most dogs. However, it may be necessary to insert the catheter between tracheal rings in giant-breed dogs to ensure that it reaches the carina. Alternatively, a 14-gauge, short, over-the-needle catheter is used to enter the trachea at the cricothyroid ligament and a 3.5F polypropylene male dog urinary catheter is passed through the catheter into the airways. The ability of the urinary catheter to pass through the 14-gauge catheter should be tested each time before the procedure is performed.

The dog can sit or lie down, depending on what position is more comfortable for the animal and clinician. The dog is restrained with its nose pointing toward the ceiling at about 45 degrees from horizontal (Fig. 20-13, A). Overextension of the neck causes the animal to be more resistant. Dogs that cannot be restrained should be tranquilized. If tranquilization is needed, premedication with atropine or glycopyrrolate is recommended to minimize contamination of the trachea with oral secretions. Narcotics are avoided to preserve the cough reflex, which can facilitate the retrieval of fluid.

The cricothyroid ligament is identified by palpating the trachea in the ventral cervical region and following it dorsally toward the larynx to the raised, smooth, narrow band of the cricoid cartilage. Immediately above the cricoid cartilage is a depression, where the cricothyroid ligament is located (Fig. 20-13, B). If the trachea is entered above the cricothyroid ligament, the catheter is passed dorsally into the pharynx and a nondiagnostic specimen is obtained. Such dorsal passage of the catheter often results in excessive gagging and retching.

Lidocaine is always injected subcutaneously at the site of entry. The skin over the cricothyroid ligament is prepared surgically, and sterile gloves are worn to pass the catheter. The needle of the catheter is held with the bevel facing ventrally. The skin over the ligament is then tented, and the needle is passed through the skin. The larynx is stabilized with the nondominant hand. To properly stabilize it, the clinician should grasp at least 180 degrees of the circumference of the airway between the fingers and thumb. Failure to hold the airway firmly is the most common technical mistake made. Next, the tip of the needle is rested against the cricothyroid ligament and inserted through the ligament with a quick, short motion.

The hand stabilizing the trachea is then used to pinch the needle at the skin, with the hand kept firmly in contact with the neck, while the catheter is threaded into the trachea with the other hand. By keeping the hand holding the needle against the neck of the animal so that the hand, needle, and neck can move as one, the clinician prevents laceration of the larynx or trachea and inadvertent removal of the needle from the trachea. Threading the catheter provokes coughing. There should be little or no resistance to the passage of the catheter. Elevating the hub of the needle slightly so that the tip points more ventrally or retracting the needle a few millimeters facilitates passage of the catheter if it is lodged against the opposite tracheal wall. The catheter itself should not be pulled back through the needle because the tip can be sheared off within the airway by the cutting edge of the needle.

Once the catheter is completely threaded into the airway, the needle is withdrawn and the catheter guard is attached to prevent shearing of the catheter. The person restraining the animal now holds the catheter guard against the neck of the animal so that movement of the neck will not dislodge the catheter. The head can be restrained in a natural position.

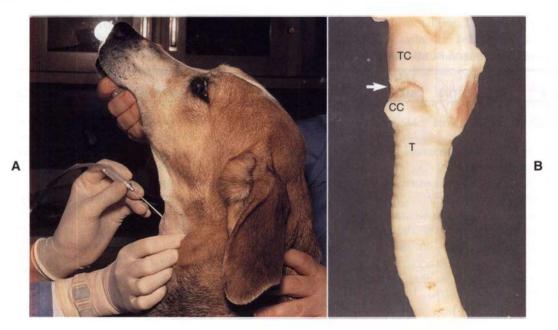

It is convenient to have four to six 12-ml syringes ready, each filled with 3 to 5 ml of 0.9% sterile preservative-free sodium chloride solution. The entire bolus of saline in one

TABLE 20-2

Comparisons of Techniques for Collecting Specimens from the Lower Respiratory Tract

TECHNIQUE	SITE OF COLLECTION	SPECIMEN SIZE	ADVANTAGES	DISADVANTAGES	INDICATIONS
Tracheal wash	Large airways	Moderate	Simple technique Minimal expense No special equipment Complications rare Volume adequate for cytology and culture	Airway must be involved for specimen to represent disease May induce bronchaspasm in patients with hyperreactive airways, particularly cats	Bronchial and alveolar disease Because of safety and ease, consider for any lung disease Less likely to be representative of interstitial or small focal processes
Bronchoalveolar lavage	Small airways, alveoli, sometimes interstitium	Large	Simple technique Nonbronchoscopic technique requires no special equipment and minimal expense Bronchoscopic technique allows airway evaluation and directed sampling Resultant hypoxemia is transient and responsive to oxygen supplementation Safe for animals in stable condition Large volume of lung sampled High cytologic quality large volume for analysis	General anesthesia required Special equipment and expertise required for bronchoscopic collection Generally not recommended for animals with increased respiratory efforts or respiratory distress Capability to provide oxygen supplementation is required May induce bronchospasm in patients with hyperreactive airways, particularly cats	Small airway, alveolar, or interstitial disease Routine during bronchoscopy
Lung aspirate	Interstitium, alveoli when flooded	Small	Simple technique Minimal expense No special equipment Solid masses adjacent to body wall: excellent representation with minimal risk	Potential for complications:    pneumothorax,    hemothorax,    pulmonary hemorrhage Relatively small area of    lung sampled Specimen adequate only    for cytology Specimen blood    contaminated	Solid masses adjacent to chest wall (for solitary/ localized disease, see also Thoracotomy or Thoracoscopy with Lung Biopsy) Diffuse interstitial disease
Thoracotomy or thoracoscopy with lung biopsy	Small airways, alveoli, interstitium	Large	Ideal specimen Allows histologic examination in addition to culture	Relatively expensive Requires expertise Requires general anesthesia Major surgical procedure	Localized process where excision may be therapeutic as well as diagnostic Any progressive disease not diagnosed by less invasive methods

#### FIG 20-13

**A,** To perform a transtracheal wash, the animal is restrained in a comfortable position with the nose pointed toward the ceiling. The ventral neck is clipped and scrubbed, and the clinician wears sterile gloves. The cricothyroid ligament is identified as described in **B.** After an injection of lidocaine, the needle of the catheter is placed through the skin. The larynx is grasped firmly with the fingers and thumb at least 180 degrees around the airway. The needle can then be inserted through the cricothyroid ligament into the airway lumen. **B,** The lateral view of this anatomic specimen demonstrates the trachea and larynx in a position similar to that of the dog in **A.** The cricothyroid ligament (arrow) is identified by palpating the trachea (T) from ventral to dorsal until the raised cricoid cartilage (CC) is palpated. The cricothyroid ligament is the first depression above the cricoid cartilage. The cricothyroid ligament attaches cranially to the thyroid cartilage (TC). The palpable depression above the thyroid cartilage (not shown) should not be entered.

syringe is injected into the catheter. Immediately after this, many aspiration attempts are made. After each aspiration, the syringe must be disconnected from the catheter and the air evacuated without losing any of the retrieved fluid. Aspirations should be forceful and repeated at least five or six times so that small volumes of airway secretions that have been aspirated into the catheter are pulled the entire length of the catheter into the syringe.

The procedure is repeated using additional boluses of saline until a sufficient amount of fluid is retrieved for analysis. A total of 1.5 to 3 ml of turbid fluid is adequate in most instances. The clinician does not need to be concerned about "drowning" the animal with the infusion of the modest volumes of fluid described because the fluid is rapidly absorbed into the circulation. Failure to retrieve adequate volumes of visibly turbid fluid can be the result of several technical difficulties, as outlined in Figure 20-14.

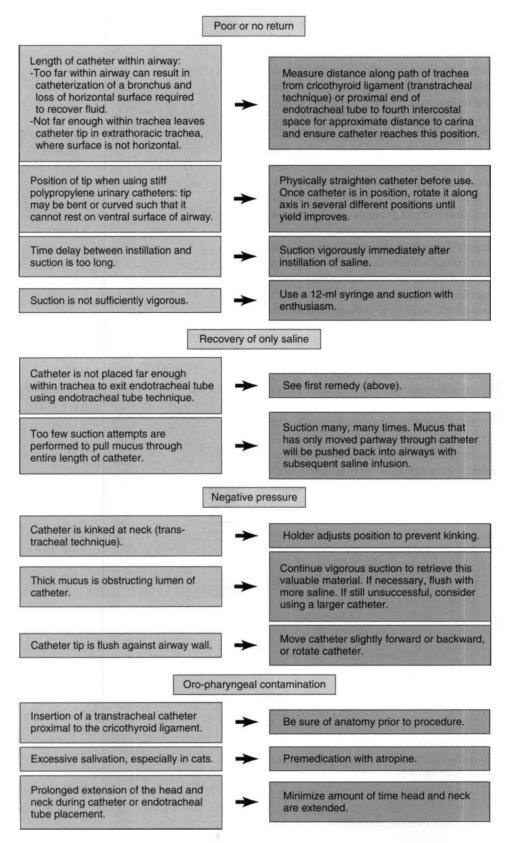

The catheter is removed after sufficient fluid is collected. A sterile gauze sponge with antiseptic ointment is then immediately placed over the catheter site, and a light bandage is wrapped around the neck. This bandage is left in place for several hours while the animal rests quietly in a cage. These precautions minimize the likelihood that subcutaneous emphysema or pneumomediastinum will develop.

### **Endotracheal Technique**

The endotracheal technique is performed by passing a 3.5-5F male dog urinary catheter through a sterilized endotracheal tube. The animal is anesthetized with a short-acting intravenous agent to a sufficient depth to allow intubation. A short-acting barbiturate, propofol, or, in cats, a combination of ketamine and acepromazine or diazepam is effective. Premedication with atropine, particularly in cats, is recommended to minimize contamination of the trachea with saliva. Cats with lower respiratory tract disease may have airway hyperreactivity and generally should be administered a bronchodilator before the tracheal wash. Terbutaline (0.01 mg/kg) can be given subcutaneously to cats not already receiving oral bronchodilators. It is also prudent to keep a metered dose inhaler of albuterol at hand to administer through the endotracheal tube or by mask if breathing becomes labored.

A sterilized endotracheal tube should be passed without dragging the tip through the oral cavity. The animal's mouth is opened wide with the tongue pulled out, a laryngoscope is used, and, in cats, sterile topical lidocaine is applied to the laryngeal cartilages to ease passage of the tube with minimal contamination.

The urinary catheter is passed through the endotracheal tube to the level of the carina (approximately the fourth

#### FIG 20-14

Overcoming problems with tracheal wash fluid collection. Green boxes indicate problems, blue boxes indicate possible causes, and orange boxes indicate remedies.

intercostal space), maintaining sterile technique. The wash procedure is performed as described for the transtracheal technique. Slightly larger boluses of saline may be required, however, because of the larger volume of the catheter. Use of a catheter larger than 5F seems to reduce the yield of the wash except when secretions are extremely viscous.

#### SPECIMEN HANDLING

The cells collected in the wash fluid are fragile. The fluid is ideally processed within 30 minutes of collection, with minimal manipulation. Bacterial culture is performed on at least 0.5 to 1 ml of fluid. Fungal cultures are performed if mycotic disease is a differential diagnosis, and Mycoplasma cultures are considered for cats and dogs with signs of bronchitis. Cytologic preparations are made both from the fluid and from any mucus within the fluid. Both fluid and mucus are examined because infectious agents and inflammatory cells can be concentrated in the mucus, but the proteinaceous material causes cells to clump and interferes with evaluation of the cell morphology. Mucus is retrieved with a needle, and squash preparations are made. Direct smears of the fluid itself can be made, but such specimens are often hypocellular. Sediment or cytocentrifuge preparations are generally necessary to make adequate interpretation possible. Straining the fluid through gauze to remove the mucus is discouraged because infectious agents may be lost in the process. Routine cytologic stains are used.

Microscopic examination of slides includes the identification of cell types, qualitative evaluation of the cells, and an examination for infectious agents. Cells are evaluated qualitatively for evidence of macrophage activation, neutrophil degeneration, lymphocyte reactivity, and characteristics of malignancy. Epithelial hyperplasia secondary to inflammation should not be overinterpreted as neoplasia, however. Infectious agents such as bacteria, protozoa (*Toxoplasma gondii*), fungi (*Histoplasma, Blastomyces*, and *Cryptococcus* organisms), and parasitic larvae or eggs may be present (see Fig. 20-12, and Figs. 20-15 through 20-17). Because only one or two organisms may be present on an entire slide, a thorough evaluation is indicated.

### INTERPRETATION OF RESULTS

Normal tracheal wash fluid contains primarily respiratory epithelial cells. Few other inflammatory cells are present (Fig. 20-18). Occasionally, macrophages are retrieved from the small airways and alveoli because the catheter was extended into the lungs beyond the carina or because relatively large volumes of saline were used. Most macrophages are not activated. In these instances the presence of macrophages does not indicate disease but rather reflects the acquisition of material from the deep lung (see the section on nonbronchoscopic bronchoalveolar lavage).

Slides are examined for evidence of overt oral contamination, which can occur during transtracheal washing if the catheter needle was inadvertently inserted proximal to the cricothyroid ligament. Rarely, dogs can cough the catheter up into the oropharynx. Oral contamination can also result

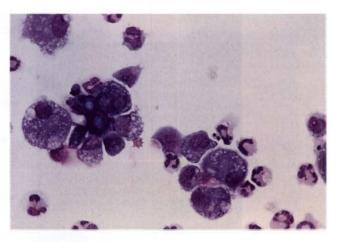

FIG 20-15

Photomicrograph of a *Blastomyces* organism from the lungs of a dog with blastomycosis. The organisms stain deeply basophilic, are 5 to 15  $\mu m$  in diameter, and have a thick refractile cell wall. Often, as in this figure, broad-based budding forms are seen. The cells present are alveolar macrophages and neutrophils. (Bronchoalveolar lavage fluid, Wright stain.)

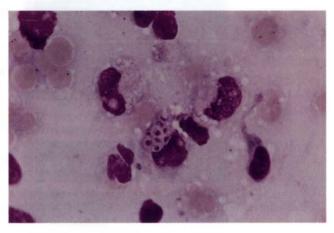

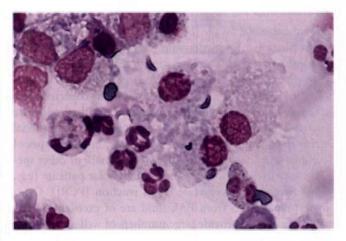

FIG 20-16

Photomicrograph of *Histoplasma* organisms from the lungs of a dog with histoplasmosis. The organisms are small (2 to 4 pm) and round, with a deeply staining center and a lighter-staining halo. They are often found within phagocytic cells: in this figure, an alveolar macrophage. (Bronchoalveolar lavage fluid, Wright stain.)

from drainage of saliva into the trachea, which usually occurs in cats that hypersalivate or dogs that are heavily sedated, particularly if the head and neck are extended more than briefly for the passage of the endotracheal tube or transtracheal catheter. Oral contamination is indicated by the finding of numerous squamous epithelial cells, often coated with bacteria, and *Simonsiella* organisms (Fig. 20-19). *Simonsiella* organisms are large basophilic rods that are frequently found stacked uniformly on one another along their broad side. Specimens with overt oral contamination generally do not provide accurate information about the airways, particularly with regard to bacterial infection.

Cytologic results of tracheal wash fluid are most useful when pathogenic organisms or malignant cells are identified. The presence of pathogens such as Toxoplasma gondii, systemic fungal organisms, and parasites provide a definitive diagnosis. The finding of bacterial organisms in cytologic preparations without evidence of oral contamination indicates the presence of infection. The growth of any of the systemic mycotic agents in culture is also clinically signifi-

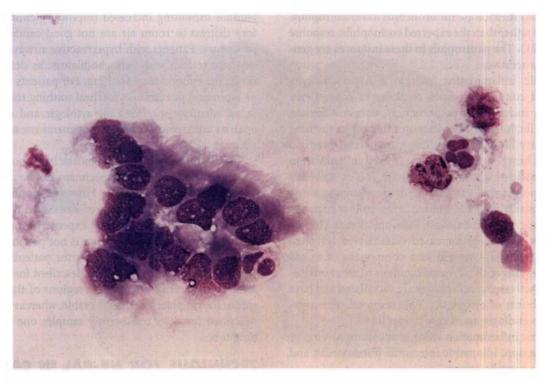

Photomicrograph of Toxoplasma gondii tachyzoites from the lungs of a cat with acute toxoplasmosis. The extracellular tachyzoites are crescent shaped with a centrally placed nucleus. They are approximately 6 µm in length. (Bronchoalveolar lavage fluid, Wright stain.)

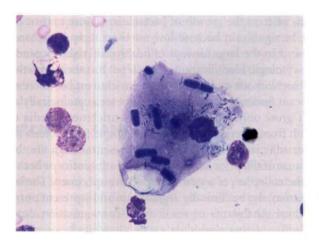

cant, whereas the growth of bacteria in culture may or may not be significant because low numbers of bacteria can be present in the large airways of healthy animals. In general, the cytologic identification of bacteria and their growth in culture without multiplication in enrichment broth are significant findings. Bacteria that are not seen cytologically and that grow only after incubation in enrichment media can result from several situations. For example, the bacteria may be causing infection without being present in high numbers because of the prior administration of antibiotics or because of the collection of a nonrepresentative specimen. The bacteria may also be clinically insignificant and represent normal tracheal inhabitants or result from contamination during collection. Other clinical data must therefore be considered when interpreting such findings. The role of *Mycoplasma* sp. in respiratory disease of the dog and cat is not well understood. These organisms cannot be seen on cytologic preparations and are difficult to grow in culture. Specific transport media is necessary. Growth of Mycoplasma organisms from tracheal wash fluid may indicate primary or secondary infection or be an insignificant finding. Treatment is generally recommended.

Criteria of malignancy for making a diagnosis of neoplasia must be interpreted with extreme caution. Overt characteristics of malignancy must be present in many cells in the absence of concurrent inflammation for a definitive diagnosis to be made.

The type of inflammatory cells present in tracheal wash fluid can assist in narrowing the differential diagnoses, although a mixed inflammatory response is common.

Tracheal wash fluid from a healthy dog showing ciliated epithelium and few inflammatory cells.

#### FIG 20-19

Tracheal wash fluid showing evidence of oropharyngeal contamination. The numerous, uniformly stacked basophilic rods are *Simonsiella* organisms, normal inhabitants of the oral cavity. These organisms, as well as many other bacteria, are adhering to a squamous epithelial cell. Squamous epithelium is another indication of contamination from the oral cavity.

Neutrophilic (suppurative) inflammation is common in bacterial infections. Before antibiotic therapy is initiated, the neutrophils may be (but are not always) degenerative, and organisms can often be seen. Neutrophilic inflammation may be a response to a variety of other diseases. For instance, it can be caused by other infectious agents or seen in patients with canine chronic bronchitis, idiopathic pulmonary fibrosis or other idiopathic interstitial pneumonias, or even neoplasia. Some cats with idiopathic bronchitis have neutrophilic inflammation rather than the expected eosinophilic response (see Chapter 21). The neutrophils in these instances are generally nondegenerative.

Eosinophilic inflammation reflects a hypersensitivity response, and common diseases resulting in eosinophilic inflammation include allergic bronchitis, parasitic disease, and eosinophilic lung disease. Parasites that affect the lung include primary lungworms or flukes, migrating intestinal parasites, and heartworms. Over time, mixed inflammation can occur in patients with hypersensitivity. It is occasionally possible for nonparasitic infections or neoplasia to cause eosinophilia, usually as part of a mixed inflammatory response.

Macrophagic (granulomatous) inflammation is characterized by the finding of increased numbers of activated macrophages, generally present as a component of mixed inflammation along with increased numbers of other inflammatory cells. Activated macrophages are vacuolated and have increased amounts of cytoplasm. This response is nonspecific unless an etiologic agent can be identified.

Lymphocytic inflammation alone is uncommon. Viral or rickettsial infection, idiopathic interstitial pneumonias, and lymphoma are considerations.

True hemorrhage can be differentiated from a traumatic specimen collection by the presence of erythrophagocytosis and hemosiderin-laden macrophages. An inflammatory response is also usually present. Hemorrhage can be caused by neoplasia, mycotic infection, heartworm disease, thromboembolism, foreign body, lung lobe torsion, or coagulopathies. Evidence of hemorrhage is seen occasionally in animals with congestive heart failure or severe bacterial pneumonia.

## NONBRONCHOSCOPIC BRONCHOALVEOLAR LAVAGE

## **Indications and Complications**

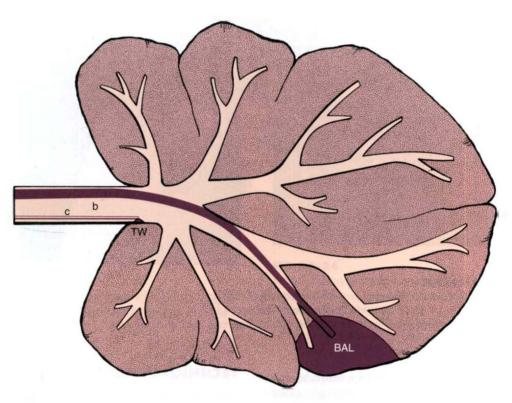

Bronchoalvelolar lavage (BAL) is considered for the diagnostic evaluation of patients with lung disease involving the small airways, alveoli, or interstitium that are not in respiratory distress (see Table 20-2). A large volume of lung is sampled by BAL (Figs. 20-20 and 20-21). The collected specimens are of large volume, providing more than adequate material for routine cytology, cytology involving special stains (e.g., Gram stains, acid-fast stains), multiple types of cultures (e.g., bacterial, fungal, mycoplasmal), or other specific tests that might be helpful in particular patients (e.g., flow cytometry, polymerase chain reaction [PCR]). Cytologic preparations from BAL fluid are of excellent quality and consistently provide large numbers of well-stained cells for examination.

Although general anesthesia is required, the procedure is associated with few complications and can be performed repeatedly in the same animal to follow the progression of disease or observe the response to therapy. The primary complication of BAL is transient hypoxemia. The hypoxemia generally can be corrected with oxygen supplementation, but animals exhibiting increased respiratory efforts or respiratory distress in room air are not good candidates for this procedure. Patients with hyperreactive airways, particularly cats, are treated with bronchodilators, as described previously, for endotracheal washing. For patients with bacterial or aspiration pneumonia, tracheal washing routinely results in an adequate specimen for cytologic and microbiologic analysis and avoids the need for general anesthesia in these patients.

BAL is a routine part of diagnostic bronchoscopy, during which visually guided BAL specimens can be collected from specific diseased lung lobes. However, nonbronchoscopic techniques (NB-BAL) have been developed that allow BAL to be performed with minimal expense in routine practice settings. Because visual guidance is not possible using these methods, they are used primarily for patients with diffuse disease. However, the technique described for cats probably samples the cranial and middle regions of the lung on the side of the cat placed against the table, whereas the technique described for dogs consistently samples one of the caudal lung lobes.

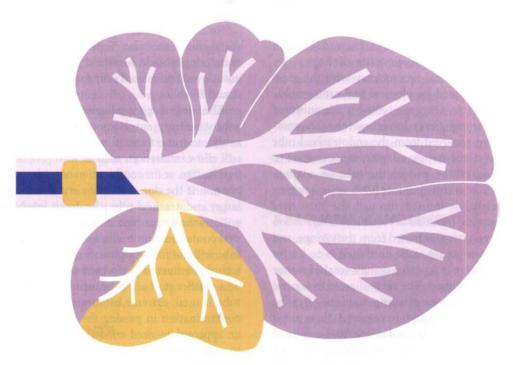

### **TECHNIQUE FOR NB-BAL IN CATS**

A sterile endotracheal tube and syringe adapter are used in cats to collect lavage fluid (Fig. 20-22; see also Fig. 20-21). Cats, particularly those with signs of bronchitis, should be

#### FIG 20-20

The region of the lower respiratory tract that is sampled by bronchoalveolar lavage (BAL) in comparison with the region sampled by tracheal wash (TW). The solid red line (b) within the airways represents a bronchoscope or modified feeding tube. The open lines (c) represent the tracheal wash catheter. Bronchoalveolar lavage yields fluid representative of the deep lung, whereas tracheal wash yields fluid representative of processes involving major airways.

#### FIG 20-21

The region of the lower respiratory tract presumed to be sampled by nonbronchoscopic bronchoalveolar lavage in cats using an endotracheal tube.

**FIG 20-22**Bronchoalveolar lavage using an endotracheal tube in a cat. The fluid retrieved is grossly foamy because of the surfactant present. The procedure is performed quickly because the airway is completely occluded during the infusion and aspiration of fluid.

treated with bronchodilators before the procedure, as described previously for tracheal wash (endotracheal technique), to decrease the risk of bronchospasm. The cat is premedicated with atropine (0.05 mg/kg subcutaneously) and anesthetized with ketamine and acepromazine or diazepam, given intravenously. The endotracheal tube is passed as cleanly as possible through the larynx to minimize oral contamination. To achieve sufficient cleanliness, the tip of the tongue is pulled out, a laryngoscope is used, and sterile lidocaine is applied topically to the laryngeal mucosa. The cuff is then inflated sufficiently to create a seal, but overinflation is avoided to prevent tracheal rupture (i.e., use a 3-ml syringe and inflate cuff in 0.5-ml increments only until no leak is audible when gentle pressure is placed on the oxygen reservoir bag).

The cat is placed in lateral recumbency with the most diseased side, as determined by physical and radiographic findings, against the table. Oxygen (100%) is administered for several minutes through the endotracheal tube. The anesthetic adapter is then removed from the endotracheal tube and replaced with a sterile syringe adapter, using caution to avoid contamination of the end of the tube or adapter. Immediately, a bolus of warmed, sterile 0.9% saline solution (5 ml/kg body weight) is infused through the tube over approximately 3 seconds. Immediately after infusion, suction is applied by syringe. Air is eliminated from the syringe, and several aspiration attempts are made until fluid is no longer recovered. The procedure is repeated using a total of two or three boluses of saline solution. The cat is allowed to expand its lungs between the infusions of saline solution. After the last infusion, the syringe adapter is removed (because it greatly interferes with ventilation) and excess fluid is drained from the large airways and endotracheal tube by elevating the caudal half of the cat a few inches off of the table. At this point, the cat is cared for as described in the section on recovery of patients after BAL.

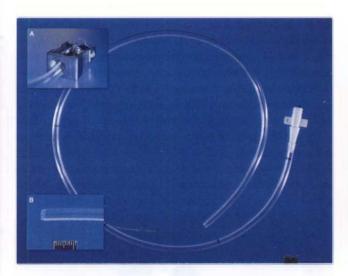

## TECHNIQUE FOR NB-BAL IN DOGS

An inexpensive 122-cm 16F Levin-type polyvinyl chloride stomach tube (Argyle stomach tube, Tyco Healthcare Group LP) can be used in dogs to collect lavage fluid. The tube must be modified for successful NB-BAL. Sterile technique is maintained throughout. The distal end of the tube is cut off to remove the side openings. The proximal end is cut off to remove the flange and shorten the tube to a length slightly greater than the distance from the open end of the dog's endotracheal tube to the last rib. A syringe adapter is placed within the proximal end of the tube (Fig. 20-23).

Recovery of BAL fluid can be improved by tapering the distal end of the tube. Tapering is readily achieved using a metal, single-blade, handheld pencil sharpener that has been autoclaved and is used only for this purpose (see Fig. 20-23, *A* and *B*).

The dog is premedicated with atropine (0.05 mg/kg subcutaneously) or glycopyrrolate (0.005 mg/kg subcutaneously) and anesthetized using a short-acting protocol that will allow intubation, such as with propofol, a short-acting barbiturate, or the combination of medetomidine and butorphanol. If the dog is of sufficient size to accept a size 6 or larger endotracheal tube, the dog is intubated with a sterile endotracheal tube placed as cleanly as possible to minimize oral contamination of the specimen. The modified stomach tube will not fit through a smaller endotracheal tube, so the technique must be performed without an endotracheal tube or a smaller stomach tube must be used. If no endotracheal tube is used, extreme care must be taken to minimize oral contamination in passing the modified stomach tube, and an appropriate-sized endotracheal tube should be available to gain control of the airway in case of complications and for recovery.

Oxygen (100%) is provided through the endotracheal tube or by face mask for several minutes. The modified

#### FIG 20-23

The catheter used for nonbronchoscopic bronchoalveolar lavage in dogs is a modified 16F Levin-type stomach tube. The tube is shortened by cutting off both ends. A simple pencil sharpener (inset A) is used to taper the distal end of the tube (inset B). A syringe adapter is added to the proximal end. Sterility is maintained throughout.

stomach tube is passed through the endotracheal tube using sterile technique until resistance is felt. The goal is to wedge the tube snugly into an airway rather than have it abut an airway division. Therefore the tube is withdrawn slightly, then passed again, until resistance is consistently felt at the same depth. Rotating the tube slightly during passage may help achieve a snug fit. Remember that if the endotracheal tube is not much larger than the stomach tube, ventilation is restricted at this point and the procedure should be completed expediently.

For medium-size dogs and larger, two 35-ml syringes are prepared in advance, each with 25 ml of saline and 5 ml of air. While the modified stomach tube is held in place, a 25-ml bolus of saline is infused through the tube, followed by the 5 ml of air, by holding the syringe upright during infusion (Fig. 20-24). Gentle suction is applied immediately after infusion, using the same syringe. It may be necessary to withdraw the tube slightly if negative pressure is felt. The tube should not be withdrawn more than a few millimeters. If it is withdrawn too far, air will be recovered instead of fluid. The second bolus of saline is infused and recovered in the same manner, with the tube in the same position. The dog is cared for as described in the next section.

In very small dogs, it is prudent to reduce the volume of saline used in each bolus, particularly if a smaller diameter stomach tube is used. Overinflation of the lungs with excessive fluid volumes should be avoided.

## RECOVERY OF PATIENTS FOLLOWING BAL

Regardless of the method used, BAL causes a transient decrease in the arterial oxygen concentration, but this hypoxemia responds readily to oxygen supplementation. Where

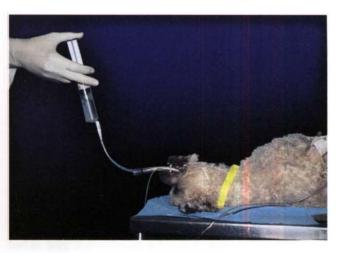

FIG 20-24

Bronchoalveolar lavage using a modified stomach tube in a dog. The tube is passed through a sterile endotracheal tube and lodged in a bronchus. A syringe preloaded with saline and air is held upright during infusion so that the saline is infused first, followed by the air.

possible, patients are monitored with pulse oximetry (p. 283) before and throughout the procedure and during recovery. After the procedure, 100% oxygen is provided through an endotracheal tube for as long as the dog or cat will allow intubation. Several gentle "sighs" are performed with the anesthesia bag to help expand any collapsed portions of lung. Bronchospasms are a reported complication of BAL in people, and increased airway resistance has been documented in cats after bronchoscopy and BAL (Kirschvink et al., 2005). Albuterol in a metered dose inhaler should be on hand to administer through the endotracheal tube or by spacer and mask if needed.

After extubation the mucous membrane color, pulses, and character of respirations are monitored closely. Crackles can be heard for several hours after BAL and are not cause for concern. Treatment with oxygen supplementation is continued by mask, oxygen cage, or nasal catheter if there are any indications of hypoxemia. Oxygen supplementation is rarely necessary for more than 10 to 15 minutes after BAL, even in animals with diseased lungs; however, the ability to provide supplementation for longer periods is a prerequisite for the performance of this procedure.

#### SPECIMEN HANDLING

Successful BAL yields fluid that is grossly foamy, a result of the surfactant from the alveoli. Approximately 50% to 80% of the total volume of saline instilled is expected to be recovered. Less will be obtained from dogs with tracheobronchomalacia (collapsing airways). The fluid is placed on ice immediately after collection and is processed as soon as possible, with minimum manipulation to decrease cell lysis. For convenience, retrieved boluses can be combined for analysis; however, fluid from the first bolus usually contains more cells from the larger airways, and fluid from later boluses is more representative of the alveoli and interstitium.

The BAL fluid is analyzed cytologically and microbiologically. Nucleated cell counts are performed on undiluted fluid using a hemocytometer. Cells are concentrated onto slides for differential cell counts and qualitative analysis using cytocentrifugation or sedimentation techniques. Excelent-quality slides result that are stained using routine cytologic procedures. Differential cell counts are performed by counting at least 200 nucleated cells. Slides are scrutinized for evidence of macrophage activation, lymphocyte reactivity, neutrophil degeneration, and criteria of malignancy. All slides are examined thoroughly for possible etiologic agents, such as fungi, protozoa, parasites, and bacteria (see Figs. 20-12 and 20-15 to 20-17). As described for tracheal wash, visible strands of mucus can be examined for etiologic agents by squash preparation.

Approximately 5 ml of fluid is used for bacterial culture. Additional fluid is submitted for fungal culture if mycotic disease is among the differential diagnoses. *Mycoplasma* cultures are considered in cats and dogs with signs of bronchitis.

#### INTERPRETATION OF RESULTS

Normal cytologic values for BAL fluid are inexact because of inconsistency in the techniques used and variability among individual animals of the same species. In general, total nucleated cell counts in normal animals are less than 400 to  $500/\mu$ l. Differential cell counts from healthy dogs and cats are listed in Table 20-3.

Interpretation of BAL fluid cytology and cultures is essentially the same as that described for tracheal wash fluid, although the specimens are more representative of the deep lung than the airways. In addition, the normal cell population of macrophages must not be misinterpreted as being indicative of macrophagic or chronic inflammation (Fig. 20-25). As for all cytologic specimens, definitive diagnoses

are made through the identification of organisms or abnormal cell populations. Fungal, protozoal, or parasitic organisms may be present in extremely low numbers in BAL specimens; therefore the entire concentrated slide preparation must be carefully scanned. Profound epithelial hyperplasia can occur in the presence of an inflammatory response and should not be confused with neoplasia.

If quantitative bacterial culture is available, growth of organisms at greater than  $1.7 \times 10^3$  colony-forming units (CFU)/ml has been reported to indicate infection (Peeters et al., 2000). In the absence of quantitative numbers, growth

<sup>\*</sup> Mean ± SD, 6 clinically and histologically normal dogs. (From Kuehn NF: Canine bronchoalveolar lavage profile. Thesis for masters of science degree, West Lafayette, Ind, 1987, Purdue University.)

<sup>†</sup> Mean ± SE, 11 clinically normal cats. (From King RR et al. Bronchoalveolar lavage cell populations in dogs and cats with eosinophilic pneumonitis. In *Proceedings of the Seventh Veterinary Respiratory Symposium*, Chicago, 1988, Comparative Respiratory Society.) ‡ Mean ± SD, 9 clinically normal dogs. (From Hawkins EC et al. Use of a modified stomach tube for bronchoalveolar lavage in dogs, *J Am Vet Med Assoc* 215:1635, 1999.)

<sup>§</sup> Mean ± SD, 34 specific pathogen-free cats. (From Hawkins EC et al: Cytologic characterization of bronchoalveolar lavage fluid collected through an endotracheal tube in cats, Am J Vet Res 55:795, 1994.)

of organisms on a plate directly inoculated with BAL fluid is considered significant, whereas growth from fluid that occurs only after multiplication in enrichment broth may also be a result of normal inhabitants or contamination. Patients that are already receiving antibiotics at the time of specimen collection may have significant infection with few or no bacteria by culture.

## DIAGNOSTIC YIELD

A retrospective study of BAL fluid cytologic analysis in dogs at referral institutions showed that BAL findings provided the basis for a definitive diagnosis in 25% of cases and were supportive of the diagnosis in an additional 50%. Only dogs in which a definitive diagnosis was obtained by any means were included. Definitive diagnoses were possible on the basis of BAL only in those animals in which infectious organisms were identified or in those cases in which overtly malignant cells were present in specimens in the absence of marked inflammation. BAL has been shown to be more sensitive than radiographs in identifying pulmonary involvement with lymphosarcoma. Carcinoma was definitively identified in 57% of cases, and other sarcomas were not found in BAL fluid. Fungal pneumonia was confirmed in only 25% of cases, although organisms were found in 67% of cases in a previous study of dogs with overt fungal pneumonia.

## TRANSTHORACIC LUNG ASPIRATION AND BIOPSY

## **Indications and Complications**

Pulmonary parenchymal specimens can be obtained by transthoracic needle aspiration or biopsy. Although only a small region of lung is sampled by these methods, collection can be guided by radiographic findings or ultrasonography to improve the likelihood of obtaining representative specimens. As with tracheal wash and BAL, a definitive diagnosis will be possible in patients with infectious or neoplastic disease. Patients with non-infectious inflammatory diseases require thoracoscopy or thoracotomy with lung biopsy for a definitive diagnosis.

Potential complications of transthoracic needle aspiration or biopsy include pneumothorax, hemothorax, and pulmonary hemorrhage. The procedures are not recommended in animals with suspected cysts, abscesses, pulmonary hypertension, or coagulopathies. Severe complications are uncommon, but these procedures should not be performed unless the clinician is prepared to place a chest tube and otherwise support the animal if necessary.

Lung aspirates and biopsy specimens are indicated for the nonsurgical diagnosis of intrathoracic mass lesions that are in contact with the thoracic wall. The risk of complications in these animals is relatively low because the specimens can be collected without disrupting aerated lung. Obtaining aspirates or biopsy specimens from masses that are far from the body wall and near the mediastinum carries the additional risk of lacerating important mediastinal organs,

vessels, or nerves. If a solitary localized mass lesion is present, thoracotomy and biopsy should be considered rather than transthoracic sampling because this permits both the diagnosis of the problem and the potentially therapeutic benefits of complete excision.

Transthoracic lung aspirates can be obtained in animals with a diffuse interstitial radiographic pattern. In some of these patients, solid areas of infiltrate in lung tissue immediately adjacent to the body wall can be identified ultrasonographically even though they are not apparent on thoracic radiographs (see Fig. 20-11). Ultrasound guidance of the aspiration needle into the areas of infiltrate should improve diagnostic yield and safety. If areas of infiltrate cannot be identified ultrasonographically, BAL should be considered before lung aspiration in animals that can tolerate the procedure because it yields a larger specimen for analysis and, in this author's opinion, carries less risk than transthoracic aspiration in patients that are not experiencing increased respiratory efforts or distress. Tracheal wash (if BAL is not possible) and appropriate ancillary tests are also generally indicated before lung aspiration in these patients because they carry little risk.

#### **TECHNIQUES**

The site of collection in animals with localized disease adjacent to the body wall is best identified with ultrasonography. If ultrasonography is not available or the lesion is surrounded by aerated lung, the site is determined on the basis of two radiographic views. The location of the lesion during inspiration in all three dimensions is identified by its relationship to external landmarks: the nearest intercostal space or rib, the distance from the costochondral junctions, and the depth into the lungs from the body wall. If available, fluoroscopy or CT also can be used to guide the needle or biopsy instrument.

The site of collection in animals with diffuse disease is a caudal lung lobe. The needle is inserted between the seventh to ninth intercostal spaces, approximately two thirds of the distance from the costochondral junctions to the spine.

The animal must be restrained for the procedure, and sedation or anesthesia is necessary in some. Anesthesia is avoided, if possible, because the hemorrhage created by the procedure is not cleared as readily from the lungs in an anesthetized dog or cat. The skin at the site of collection is shaved and surgically prepared. Lidocaine is injected into the subcutaneous tissues and intercostal muscles to provide local anesthesia.

Lung aspiration can be performed with an injection needle, spinal needle, or a variety of thin-walled needles designed specifically for lung aspiration in people. Spinal needles are readily available in most practices, are sufficiently long to penetrate through the thoracic wall, and have a stylet. A 22-gauge, 1.5- to 3.5-inch (3.75- to 8.75-cm) spinal needle is usually adequate.

The clinician wears sterile gloves. The needle with stylet is advanced through the skin several rib spaces from the desired biopsy site. The needle and skin are then moved to the biopsy site. This is done because air is less likely to enter the thorax through the needle tract following the procedure if the openings in the skin and chest wall are not aligned. The needle is then advanced through the body wall to the pleura. The stylet is removed, and the needle hub is immediately covered by a finger to prevent pneumothorax until a 12-ml syringe can be placed on the hub. During inspiration the needle is thrust into the chest to a depth predetermined from the radiographs, usually about 1 inch (2.5 cm), while suction is applied to the syringe (Fig. 20-26). To keep from inserting the needle too deeply, the clinician may pinch the needle shaft with the thumb and forefinger of the nondominant hand at the desired maximum depth of insertion. During insertion the needle can be twisted along its long axis in an attempt to obtain a core of tissue. The needle is then immediately withdrawn to the level of the pleura. Several quick stabs into the lung can be made along different lines to increase the yield.

Each stab should take only a second. Prolonging the time that the needle is within the lung tissue increases the likelihood of complications. The lung tissue will be moving with respirations, resulting in laceration of tissue, even if the needle is held steady.

The needle is withdrawn from the body wall with a minimal amount of negative pressure maintained by the syringe. It is unusual for the specimen to be large enough to have entered the syringe. The needle is removed from the syringe, the syringe is filled with air and reattached to the

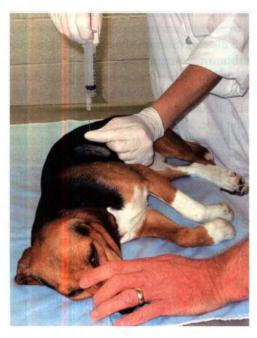

FIG 20-26

Transthoracic lung aspiration performed with a spinal needle. Note that sterile technique is used. The needle shaft can be pinched with a finger and thumb at the maximum depth to which the needle should be passed. The finger and thumb thus act as a guard to prevent overinsertion of the needle. Although this patient is under general anesthesia, this is not usually indicated.

needle, and the contents of the needle are then forced onto one or more slides. Grossly, the material is bloody in most cases. Squash preparations are made. Slides are stained using routine procedures and then evaluated cytologically. Increased numbers of inflammatory cells, infectious agents, or neoplastic cell populations are potential abnormalities. Alveolar macrophages are normal findings in parenchymal specimens and should not be interpreted as representing chronic inflammation. They should be carefully examined for evidence of phagocytosis of bacteria, fungi, or red blood cells and for signs of activation. Epithelial hyperplasia can occur in the presence of inflammation and should not be confused with neoplasia. Sometimes the liver is aspirated inadvertently, particularly in deep-chested dogs, yielding a population of cells that may resemble those from adenocarcinoma. However, hepatocytes typically contain bile pigment. Bacterial culture is indicated in some animals, although the volume of material obtained is quite small.

Transthoracic lung core biopsies can be performed in animals with mass lesions. They are collected after an aspirate has proved to be nondiagnostic. Needle biopsy instruments can be used to biopsy lesions adjacent to the chest wall (e.g., EZ Core biopsy needles, Products Group International). Smaller-bore, thin-walled lung biopsy instruments can be obtained from medical suppliers for human patients. These instruments collect smaller pieces of tissue but are less disruptive to normal lung. Ideally, sufficient material is collected for histologic evaluation. If not, squash preparations are made for cytologic studies.

#### **BRONCHOSCOPY**

## **Indications**

Bronchoscopy is indicated for the evaluation of the major airways in animals with suspected structural abnormalities, for visual assessment of airway inflammation or pulmonary hemorrhage, and as a means of collecting specimens in animals with undiagnosed lower respiratory tract disease. Bronchoscopy can be used to identify structural abnormalities of the major airways, such as tracheal collapse, mass lesions, tears, strictures, lung lobe torsions, bronchiectasis, bronchial collapse, and external airway compression. Foreign bodies or parasites may be identified. Hemorrhage or inflammation involving or extending to the large airways may also be seen and localized.

Specimen collection techniques performed in conjunction with bronchoscopy are valuable diagnostic tools because they can be used to obtain specimens from deeper regions of the lung than is possible with the tracheal wash technique, and visually directed sampling of specific lesions or lung lobes is also possible. Animals undergoing bronchoscopy must receive general anesthesia, and the presence of the scope within the airways compromises ventilation. Therefore bronchoscopy is contraindicated in animals with severe respiratory tract compromise unless the procedure is likely to be therapeutic (e.g., foreign body removal).

## **Technique**

Bronchoscopy is technically more demanding than most other endoscopic techniques. The patient is often experiencing some degree of respiratory compromise, which poses increased anesthetic and procedural risk. Airway hyperreactivity may be exacerbated by the procedure, particularly in cats.(Kirschvink et al., 2005) A small-diameter, flexible endoscope is needed and should be sterilized before use. The bronchoscopist should be thoroughly familiar with normal airway anatomy to ensure that every lobe is examined. BAL is routinely performed as part of diagnostic bronchoscopy after thorough visual examination of the airways. The reader is referred to chapters in other textbooks for details about performing bronchoscopy and bronchoscopic BAL (Kuehn, 2004; McKiernan, 2005; Hawkins, 2004). Bronchoscopic images of normal airways are shown in Fig. 20-27. Reported cell counts from bronchoscopically collected BAL fluid are provided in Table 20-3.

Abnormalities that may be observed during bronchoscopy and their common clinical correlations are listed in Table 20-4. A definitive diagnosis may not be possible on the basis of the findings yielded by gross examination alone. Specimens are collected through the biopsy channel for cytologic, histopathologic, and microbiologic analysis. Bronchial specimens are obtained by bronchial washing, bronchial brushing, or pinch biopsy. Material for bacterial culture can be collected with guarded culture swabs. The deeper lung is sampled by BAL or transbronchial biopsy. Foreign bodies are removed with retrieval forceps.

# THORACOTOMY OR THORACOSCOPY WITH LUNG BIOPSY

Thoracotomy and surgical biopsy are performed in animals with progressive clinical signs of lower respiratory tract disease that has not been diagnosed using less invasive means. Although thoracotomy carries a greater risk than the previously mentioned diagnostic techniques, the modern anesthetic agents, surgical techniques, and monitoring capabilities now available have made this procedure routine in many veterinary practices. Analgesic drugs are used to manage the postoperative pain, and complication-free animals are discharged as soon as 2 to 3 days after surgery. Surgical biopsy provides excellent-quality specimens for histopathologic analysis and culture. Abnormal lung tissue and accessible lymph nodes are biopsied.

Excisional biopsy of abnormal tissue can be therapeutic in animals with localized disease. Removal of localized neoplasms, abscesses, cysts, and foreign bodies can be curative. The removal of large localized lesions can improve the matching of ventilation and perfusion, even in animals with evidence of diffuse lung involvement, thereby improving the oxygenation of blood and reducing clinical signs.

In practices where thoracoscopy is available, this less invasive technique can be used for initial assessment of intrathoracic disease. Similarly, a "mini" thoracotomy through a

relatively small incision can be performed. If disease is obviously disseminated throughout the lungs such that surgical intervention will not be therapeutic, biopsies of abnormal tissue can be obtained with these methods via small incisions. For patients with questionable findings or apparently localized disease, thoracoscopy or "mini" thoracotomy can be transitioned to a full thoracotomy during the same anesthesia.

## **BLOOD GAS ANALYSIS**

#### **Indications**

The measurement of partial pressures of oxygen (PaO<sub>2</sub>) and carbon dioxide (PaCO<sub>2</sub>) in arterial blood specimens provides information about pulmonary function. Venous blood analysis is less useful because venous blood oxygen pressures are greatly affected by cardiac function and peripheral circulation. Arterial blood gas measurements are indicated to document pulmonary failure, to differentiate hypoventilation from other causes of hypoxemia, to help determine the need for supportive therapy, and to monitor the response to therapy. Respiratory compromise must be severe for abnormalities to be measurable because the body has tremendous compensatory mechanisms.

#### **TECHNIQUES**

Arterial blood is collected in a heparinized syringe. Dilution of specimens with liquid heparin can alter blood gas results. Therefore commercially available syringes preloaded with lyophilized heparin are recommended (e.g., Micro ABG<sup>TM</sup>, 1-ml luer slip syringe with 25-g needle and 50 U heparin, Vital Signs, Inc). Alternatively, the procedure for heparinizing syringes as described by Hopper et al. (2005) should be followed: 0.5 ml of liquid sodium heparin is drawn into a 3-ml syringe with a 25 g needle. The plunger is drawn back to the 3 ml mark. All air is then expelled from the syringe. This procedure for expelling air and excess heparin is repeated three times.

The femoral artery is commonly used (Fig. 20-28). The animal is placed in lateral recumbency. The upper rear limb is abducted, and the rear limb resting on the table is restrained in a partially extended position. The femoral artery is palpated in the inguinal region, close to the abdominal wall, using two fingers. The needle is advanced into the artery between these fingers. The artery is thick walled and loosely attached to adjacent tissues; thus the needle must be sharp and positioned exactly on top of the artery. A short, jabbing motion facilitates entry.

The dorsal pedal artery is useful for arterial collection in medium-sized and large dogs. The position of the artery is illustrated in Fig. 20-29.

Once the needle has penetrated the skin, suction is applied. On entry of the needle into the artery, blood should enter the syringe quickly, sometimes in pulses. Unless the animal is severely compromised, the blood will be bright red compared with the dark red of venous blood. Dark red blood

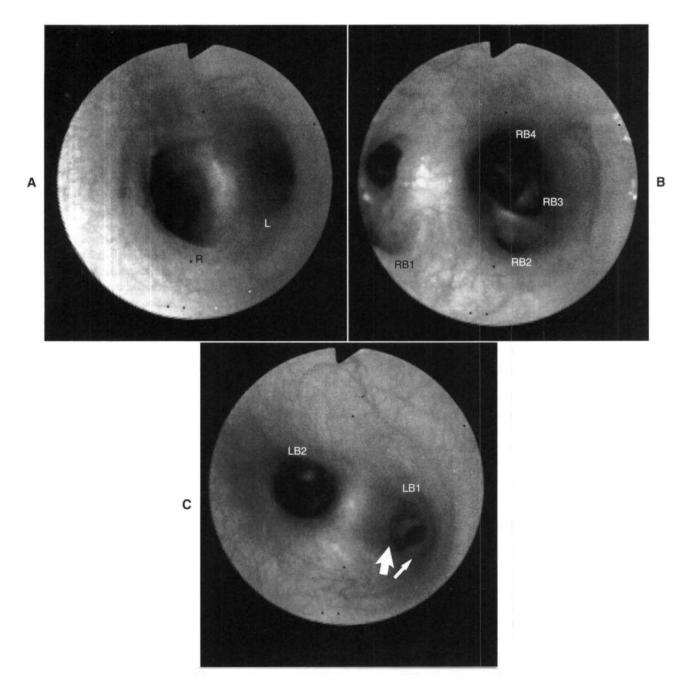

FIG 20-27

Bronchoscopic images of normal airways. The labels for the lobar bronchi are from a useful nomenclature system for the major airways and their branches by Amis et al. (1986). **A,** Carina, the division between the right (R) and left (L) mainstem bronchi. **B,** Right mainstem bronchus. The carina is off the right side of the image. The openings to the right cranial (RB1), right middle (RB2), accessory (RB3), and right caudal (RB4) bronchi are visible. **C,** Left mainstem bronchus. The carina is off the left side of the image. The openings to the left cranial (LB1) and left caudal (LB2) bronchi are visible. The left cranial lobe (LB1) divides immediately into cranial (narrow arrow) and caudal (broad arrow) branches. (Amis TC et al: Systematic identification of endobronchial anatomy during bronchoscopy in the dog, Am J Vet Res 47:2649, 1986.)

or blood that is difficult to draw into the syringe may be from a vein. Mixed samples from both the artery and vein can also be collected accidentally, particularly from the femoral site.

After removal of the needle, pressure is applied to the puncture site for 5 minutes to prevent hematoma formation.

Pressure is applied even after unsuccessful attempts if there is any possibility that the artery was entered.

All air bubbles are eliminated from the syringe. The needle is covered by a cork or rubber stopper, and the entire syringe is placed in crushed ice unless the blood specimen is

**TABLE 20-4** 

## Bronchoscopic Abnormalities and Their Clinical Correlations

#### **ABNORMALITY**

#### Trachea

Hyperemia, loss of normal vascular pattern, excess mucus, exudate

Redundant tracheal membrane Flattened cartilage rings Uniform narrowing Strictures

Mass lesions Tears

#### Carina

Widened Multiple raised nodules Foreign body

#### Bronchi

Hyperemia, excess mucus, exudate
Collapse of airway during expiration
Collapse of airway, inspiration and expiration, ability
to pass scope through narrowed airway
Collapse of airway, inspiration and expiration, inability
to pass scope through narrowed airway
Collapse of airway with "puckering" of mucosa
Hemorrhage

Single mass lesion Multiple polypoid masses Foreign body

## CLINICAL CORRELATION

Inflammation

Tracheal collapse Tracheal collapse Hypoplastic trachea Prior trauma

Fractured rings, foreign body granuloma, neoplasia
Usually caused by excessive endotracheal tube cuff pressure

Hilar lymphadenopathy, extraluminal mass Oslerus osleri Foreign body

Inflammation

Chronic inflammation, bronchomalacia Chronic inflammation, bronchomalacia

Extraluminal mass lesions (neoplasia, granuloma, abscess)

Lung lobe torsion

Neoplasia, fungal infection, heartworm, thromboembolic disease, coagulopathy, trauma (including foreign body related)

Neoplasia

Usually chronic bronchitis; at carina, Oslerus

Foreign body

#### FIG 20-28

Position for obtaining an arterial blood specimen from the femoral artery. The dog is in left lateral recumbency. The right rear limb is being held perpendicular to the table to expose the left inguinal area. The pulse is palpated in the femoral triangle between two fingers to accurately locate the artery. The needle is laid directly on top of the artery, then stabbed into it with a short, jabbing motion.

to be analyzed immediately. Specimens should be analyzed as soon as possible after collection. Minimal alterations occur in specimens stored on ice during the few hours required to transport the specimen to a human hospital if a blood gas analyzer is not available on site. Because of the availability of reasonably priced blood gas analyzers, point-of-care testing is now possible.

## INTERPRETATION OF RESULTS

Approximate arterial blood gas values for normal dogs and cats are provided in Table 20-5. More exact values should be obtained for normal dogs and cats using the actual analyzer.

## Pao<sub>2</sub> and Paco<sub>2</sub>

Abnormal PaO<sub>2</sub> and PaCO<sub>2</sub> values can result from technical error. The animal's condition and the collection technique are considered in the interpretation of blood gas values. For example, an animal in stable condition with normal mucous membrane characteristics being evaluated for exercise intolerance is unlikely to have a resting PaO<sub>2</sub> of 45 mm Hg. The

FIG 20-29

Position for obtaining an arterial blood specimen from the dorsal pedal artery. The dog is in left lateral recumbency, with the medial surface of the left leg exposed. A pulse is palpated just below the tarsus on the dorsal surface of the metatarsus between the midline and the medial aspect of the distal limb.

**TABLE 20-5** 

Approximate Ranges of Arterial Blood Gas Values for Normal Dogs and Cats Breathing Room Air

MEASUREMENT	ARTERIAL BLOOD	
PaO <sub>2</sub> (mm Hg)	85-100	
PaCO <sub>2</sub> (mm Hg)	35-45	
HCO <sub>3</sub> (mmol/L)	21-27	
рН	7.35-7.45	

collection of venous blood is a more likely explanation for this abnormal value.

Hypoxemia is present if the PaO<sub>2</sub> is below the normal range. The oxyhemoglobin dissociation curve describing the relationship between the saturated hemoglobin level and

PaO<sub>2</sub> is sigmoid in shape, with a plateau at higher PaO<sub>2</sub> values (Fig. 20-30). Normal hemoglobin is almost totally saturated with oxygen when the PaO<sub>2</sub> is greater than 80 to 90 mm Hg, and clinical signs are unlikely in animals with such values. The curve begins to decrease more quickly at lower PaO<sub>2</sub> values. A value of less than 60 mm Hg corresponds to a hemoglobin saturation that is considered dangerous, and treatment for hypoxemia is indicated. (See the section on oxygen content, delivery, and utilization [p. 282] for further discussion.)

In general, animals become cyanotic when the PaO<sub>2</sub> reaches 50 mm Hg or less, which results in a concentration of nonoxygenated (unsaturated) hemoglobin of 5 g/dl or more. Cyanosis occurs as a result of the increased concentration of nonoxygenated hemoglobin in the blood and is not a direct reflection of the PaO<sub>2</sub>. The development of cyanosis depends on the total concentration of hemoglobin, as well as the oxygen pressure; cyanosis develops more quickly in animals with polycythemia than in animals with anemia. Acute hypoxemia resulting from lung disease more often produces pallor in an animal than cyanosis. Treatment for hypoxemia is indicated for all animals with cyanosis.

Determining the mechanism of hypoxemia is useful in selecting appropriate supportive therapy. These mechanisms include hypoxentilation, inequality of ventilation and perfusion within the lung, and diffusion abnormality. Hypoxentilation is the inadequate exchange of gases between the outside of the body and the alveoli. The PaO<sub>2</sub> and PaCO<sub>2</sub> are both affected by a lack of gas exchange, and hypercapnia occurs in conjunction with hypoxemia. Causes of hypoxentilation are listed in Box 20-9.

The ventilation and perfusion of different regions of the lung must be matched for the blood leaving the lung to be fully oxygenated. The relationship between ventilation (V) and perfusion (Q) can be described as a ratio (V/Q). Hypoxemia can develop if there are regions of lung with either a low or a high V/Q.

Poorly ventilated portions of lung with normal blood flow have a low V/Q. Regionally decreased ventilation occurs in most pulmonary diseases for reasons such as alveolar flooding, alveolar collapse, or small airway obstruction. The flow of blood past totally nonaerated tissue is known as a venous admixture or shunt (V/Q of zero). The alveoli may be unventilated as a result of complete filling or collapse, resulting in physiologic shunts, or the alveoli may be bypassed by true anatomic shunts. Unoxygenated blood from these regions then mixes with oxygenated blood from ventilated portions of the lung. The immediate result is a decreased PaO2 and an increased PaCO2. The body responds to the hypercapnia by increasing ventilation, effectively returning the PaCO<sub>2</sub> to normal or even lower than normal. However, the increased ventilation cannot correct the hypoxemia because blood flowing by ventilated alveoli is already maximally saturated.

Except where shunts are present, the PaO<sub>2</sub> can be improved in dogs and cats with lung regions with low V/Q by providing supplemental oxygen therapy administered by face mask,

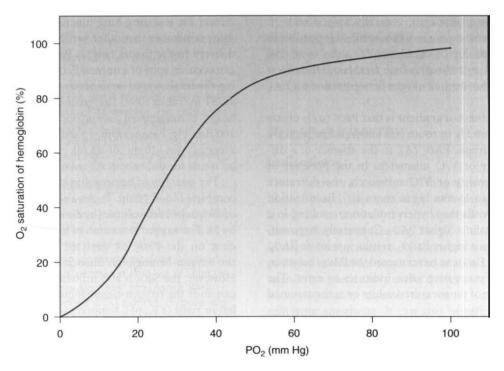

FIG 20-30 Oxygen-hemoglobin dissociation curve (approximation).

BOX 20-9

Clinical Correlations of Blood Gas Abnormalities

## Decreased PaO<sub>2</sub> and Increased PaCO<sub>2</sub> (Normal A-a Gradient)

Venous specimen

Hypoventilation

Airway obstruction

Decreased ventilatory muscle function

- Anesthesia
- Central nervous system disease
- Polyneuropathy
- Polymyopathy
- Neuromuscular junction disorders (myasthenia aravis)
- Extreme fatigue (prolonged distress)

Restriction of lung expansion

- · Thoracic wall abnormality
- Excessive thoracic bandage
- Pneumothorax
- Pleural effusion

Increased dead space (low alveolar ventilation)

 Severe chronic obstructive pulmonary disease/ emphysema

End-stage severe pulmonary parenchymal disease Severe pulmonary thromboembolism

## Decreased PaO<sub>2</sub> and Normal or Decreased PaCO<sub>2</sub> (Wide A-a Gradient)

Ventilation/perfusion (V/Q) abnormality

Most lower respiratory tract diseases (see Table 19-1,
p. 248)

oxygen cage, or nasal catheter. Positive-pressure ventilation may be necessary to combat atelectasis (see Chapter 27).

The ventilation of areas of lung with decreased circulation (a high V/Q) occurs in dogs and cats with thromboembolism. Initially there may be little effect on arterial blood gas values because blood flow is shifted to unaffected regions of the lung. However, blood flow in the normal regions of the lungs increases with increasing severity of disease, and V/Q is decreased enough in those regions that a decreased PaO<sub>2</sub> and a normal or decreased PaCO<sub>2</sub> occur, as described previously. Both hypoxemia and hypercapnia are seen in the setting of extremely severe embolization.

Diffusion abnormalities alone do not result in clinically significant hypoxemia but can occur in conjunction with V/Q mismatching in diseases such as idiopathic pulmonary fibrosis and noncardiogenic pulmonary edema. Gas is normally exchanged between the alveoli and the blood by diffusing across the respiratory membrane. This membrane consists of the fluid lining the alveolus, alveolar epithelium, alveolar basement membrane, interstitium, capillary basement membrane, and capillary endothelium. Gases must also diffuse through plasma and red blood cell membranes. Functional and structural adaptations that facilitate diffusion between the alveoli and red blood cells provide an efficient system for this process, which is rarely affected significantly by disease.

## A-a Gradient

Hypoventilation is differentiated from  $\dot{V}/\dot{Q}$  abnormalities by evaluating the PaCO<sub>2</sub> in conjunction with the PaO<sub>2</sub>. Qualitative differences are described in the preceding paragraphs: hypoventilation is associated with hypoxemia and hypercap-

nia, and  $\dot{V}/\dot{Q}$  abnormalities are generally associated with hypoxemia and normocapnia or hypocapnia. It is possible to quantify this relationship by calculating the alveolar-arterial oxygen gradient (*A-a* gradient), which factors out the effects of ventilation and the inspired oxygen concentration on PaO<sub>2</sub> (Table 20-6).

The premise of the A-a gradient is that  $PaO_2$  (a) is nearly equal (within 10 mm Hg in room air) to the partial pressure of oxygen in the alveoli,  $PAO_2$  (A), in the absence of a diffusion abnormality or  $\dot{V}/\dot{Q}$  mismatch. In the presence of a diffusion abnormality or  $\dot{V}/\dot{Q}$  mismatch, the difference widens (greater than 15 mm Hg in room air). Examination of the equation reveals that hyperventilation, resulting in a lower  $PaCO_2$ , results in a higher  $PaCO_2$ . Conversely, hypoventilation, resulting in a higher  $PaCO_2$ , results in a lower  $PAO_2$ . Physiologically the  $PaO_2$  can never exceed the  $PAO_2$ , however, and the finding of a negative value indicates an error. The error may be in one of the measured values or in the assumed R value (see Table 20-6).

Clinical examples of the calculation and interpretation of the *A-a* gradient are provided in Box 20-10.

## Oxygen Content, Delivery, and Utilization

The commonly reported blood gas value PaO<sub>2</sub> reflects the pressure of oxygen dissolved in arterial blood. This value is

critical for assessing lung function. However, the clinician must remember that other variables are involved in oxygen delivery to the tissues besides PaO<sub>2</sub> and that tissue hypoxia can occur in spite of a normal PaO<sub>2</sub>. The formula for calculating the total oxygen content of arterial blood (CaO<sub>2</sub>) is provided in Table 20-6. The greatest contribution to CaO<sub>2</sub> in health is oxygenated hemoglobin. In a normal dog (PaO<sub>2</sub>, 100 mm Hg; hemoglobin, 15 g/dl), oxygenated hemoglobin accounts for 20 ml of O<sub>2</sub>/dl, whereas dissolved oxygen accounts for only about 0.3 ml of O<sub>2</sub>/dl.

The quantity of hemoglobin is routinely appraised by the complete blood count. It can also be estimated on the basis of the packed cell volume (by dividing the packed cell volume by 3). The oxygen saturation of hemoglobin (SaO<sub>2</sub>) is dependent on the PaO<sub>2</sub>, as depicted by the sigmoid shape of the oxygen-hemoglobin dissociation curve (see Fig. 20-30). However, the SaO<sub>2</sub> is also influenced by other variables that can shift the oxygen-hemoglobin dissociation curve to the left or right (e.g., pH, temperature, or 2,3-diphosphoglycerate concentrations) or interfere with oxygen binding with hemoglobin (e.g., carbon monoxide toxicity or methemoglobinemia). Some laboratories measure SaO<sub>2</sub>.

Oxygen must also be successfully delivered to the tissues, and this depends on cardiac output and local circulation. Ultimately, the tissues must be able to effectively utilize the

TABLE 20-6

Relationships of Arterial Blood Gas Measurements

#### **FORMULA** DISCUSSION Pao<sub>2</sub> ∝ Sao<sub>2</sub> Relationship is defined by sigmoid oxygen-hemoglobin dissociation curve. Curve plateaus at greater than 90% Sao<sub>2</sub> with Pao<sub>2</sub> values greater than 80 mm Hg. Curve is steep at Pao<sub>2</sub> values of between 20 and 60 mm Hg. (Assuming normal hemoglobin, pH, temperature, and 2,3-diphosphoglycerate concentrations.) Total oxygen content of blood is greatly influenced by Sao<sub>2</sub> and hemoglobin $Cao_2 = (Sao_2 \times Hgb \times 1.34) +$ concentration. In health, more than 60 times more oxygen is delivered by $(0.003 \times Pao_2)$ hemoglobin than is dissolved in plasma (Pao<sub>2</sub>). $Paco_2 = PAco_2$ These values are increased with hypoventilation at alveolar level and decreased with hypoventilation. $PAo_2 = Flo_2 (P_B - PH_2O) - Paco_2/R$ Partial pressure of oxygen in alveolar air available for exchange with blood on room air at sea level: PAo<sub>2</sub> = changes directly with inspired oxygen concentration and inversely with Paco<sub>2</sub>. $150 \text{ mm Hg} - \text{Paco}_2/0.8$ R is assumed to be 0.8 for fasting animals. With normally functioning lungs (minimal V/Q mismatch), alveolar hyperventilation results in increased PAo<sub>2</sub> and subsequently increased Pao<sub>2</sub>, whereas hypoventilation results in decreased PAo<sub>2</sub> and decreased Pao<sub>2</sub>. $A-a = PAo_2 - Pao_2$ A-a gradient quantitatively assesses V/Q mismatch by eliminating contribution of alveolar ventilation and inspired oxygen concentration to measured Pao<sub>2</sub>. Low Pao<sub>2</sub>, with a normal A-a gradient (10 mm Hg in room air) indicates hypoventilation alone. Low Pao2 with a wide A-a gradient (>15 mm Hg in room air) indicates a component of V/Q mismatch. Paco<sub>2</sub> ∞ 1/pH Increased Paco<sub>2</sub> causes respiratory acidosis; decreased Paco<sub>2</sub> causes respiratory alkalosis. Actual pH depends on metabolic (HCO3) status as well.

BOX 20-10

## Calculation and Interpretation of A-a Gradient: Clinical Examples

Example 1: A healthy dog breathing room air has a  $PaO_2$  of 95 mm Hg and a  $PaCO_2$  of 40 mm Hg. His calculated  $PAO_2$  is 100 mm Hg. ( $PAO_2 = FIO_2$  [ $P_B - PH_2O$ ]  $- PaCO_2/R = 0.21$  [765 mm Hg - 50 mm Hg] - [40 mm Hg/0.8].] The A-a gradient is 100 mm Hg - 95 mm Hg = 5 mm Hg. This value is normal.

Example 2: A dog with respiratory depression due to an anesthetic overdose has a PaO<sub>2</sub> of 72 mm Hg and a PaCO<sub>2</sub> of 56 mm Hg in room air. His calculated PAO<sub>2</sub> is 80 mm Hg. The A-a gradient is 8 mm Hg. His hypoxemia can be explained by hypoventilation.

Later the same day, the dog develops crackles bilaterally. Repeat blood gas analysis shows a PaO<sub>2</sub> of 60 mm Hg and a PaCO<sub>2</sub> of 48 mm Hg. His calculated PAO<sub>2</sub> is 90 mm Hg. The A-a gradient is 30 mm Hg. Hypoventilation continues to contribute to the hypoxemia, but hypoventilation has improved. The widened A-a gradient indicates V/Q mismatch. This dog has aspirated gastric contents into his lungs.

oxygen—a process interfered with in the presence of toxicities such as carbon monoxide or cyanide poisoning. Each of these processes must be considered when interpreting the blood gas values in an individual animal.

## **Acid-Base Status**

The acid-base status of an animal can also be assessed using the same blood sample as that used to measure blood gases. Acid-base status is influenced by the respiratory system (see Table 20-6). Respiratory acidosis results if carbon dioxide is retained as a result of hypoventilation. If the problem persists for several days, compensatory retention of bicarbonate by the kidneys occurs. Excess removal of carbon dioxide by the lungs caused by hyperventilation results in respiratory alkalosis. Hyperventilation is usually an acute phenomenon, potentially caused by shock, sepsis, severe anemia, anxiety, or pain; therefore compensatory changes in the bicarbonate concentration are rarely seen.

The respiratory system partially compensates for primary metabolic acid-base disorders, and this can occur quickly. Hyperventilation and a decreased PaCO<sub>2</sub> occur in response to metabolic acidosis. Hypoventilation and an increased PaCO<sub>2</sub> occur in response to metabolic alkalosis.

In most cases, acid-base disturbances can be identified as primarily respiratory or primarily metabolic in nature on the basis of the pH. The compensatory response will never be excessive and alter the pH beyond normal limits. An animal with acidosis (pH of less than 7.35) has a primary respiratory acidosis if the PaCO<sub>2</sub> is increased and a compensatory respiratory response if the PaCO<sub>2</sub> is decreased. An animal with alkalosis (pH of greater than 7.45) has a primary respiratory alkalosis if the PaCO<sub>2</sub> is decreased and a compensatory respiratory response if the PaCO<sub>2</sub> is increased.

If both the  $PaCO_2$  and the bicarbonate concentration are abnormal, such that both contribute to the same alteration in pH, a mixed disturbance is present. For instance, an animal with acidosis, an increased  $PaCO_2$ , and a decreased  $HCO_3$  has a mixed metabolic and respiratory acidosis.

## **PULSE OXIMETRY**

#### **Indications**

Pulse oximetry is a method of monitoring the oxygen saturation of blood. The saturation of hemoglobin with oxygen is related to the PaO<sub>2</sub> by the sigmoid oxygen-hemoglobin dissociation curve (see Fig. 20-30). Pulse oximetry is noninvasive, can be used to continuously monitor a dog or cat, provides immediate results, and is affordable for most practices. It is a particularly useful device for monitoring animals with respiratory disease that must undergo procedures requiring anesthesia. It can also be used in some cases to monitor the progression of disease or the response to therapy. More and more clinicians are using these devices for the routine monitoring of animals under general anesthesia, particularly if the number of personnel is limited, because alarms can be set to warn of marked changes in values.

#### METHODOLOGY

Most pulse oximeters have a probe that is attached to a fold of tissue, such as the tongue, lip, ear flap, inguinal skin fold, toe, or tail (Fig. 20-31). This probe measures light absorption through the tissues. Other models measure reflected light and can be placed on mucous membranes or within the esophagus or rectum. Artifacts resulting from external light sources are minimized in the latter sites. Arterial blood is identified by the oximeter as that component which changes in pulses. Nonpulsatile absorption is considered background.

### INTERPRETATION

Values provided by the pulse oximeter must be interpreted with care. The instrument must record a pulse that matches the palpable pulse of the animal. Any discrepancy between the actual pulse and the pulse received by the oximeter indicates an inaccurate reading. Common problems that can interfere with the accurate detection of pulses include the position of the probe, animal motion (e.g., respirations, shivering), and weak or irregular pulse pressures (e.g., tachycardia, hypovolemia, hypothermia, arrhythmias).

The value measured indicates the saturation of hemoglobin in the local circulation. However, this value can be affected by factors other than pulmonary function, such as vasoconstriction, low cardiac output, and the local stasis of blood. Other intrinsic factors that can affect oximetry readings include anemia, hyperbilirubinemia, carboxyhemoglobinemia, and methemoglobinemia. External lights and the location of the probe can also influence results. Pulse oximetry readings of oxygen saturation are less accurate below values of 80%.

These sources for error should not discourage the clinician from using this technology, however, because changes

FIG 20-31
Monitoring oxygen saturation in a cat under general anesthesia using a pulse oximeter with a probe (P) clamped on the tongue (T).

in saturation in an individual animal provide valuable information. Rather, results must be interpreted critically.

The examination of the oxygen-hemoglobin dissociation curve (see Fig. 20-30) in normal dogs and cats shows that animals with PaO<sub>2</sub> values exceeding 85 mm Hg will have a hemoglobin saturation greater than 95%. If PaO<sub>2</sub> values decrease to 60 mm Hg, the hemoglobin saturation will be approximately 90%. Any further decrease in PaO2 results in a precipitous decrease in hemoglobin saturation, illustrated by the steep portion of the oxygen-hemoglobin dissociation curve. Ideally, then, hemoglobin saturation should be maintained at more than 90% by means of oxygen supplementation or ventilatory support (see Chapter 27) or the specific treatment of the underlying disease. However, because of the many variables associated with pulse oximetry, such strict guidelines are not always valid. In practice, a baseline hemoglobin saturation value is measured and subsequent changes in that value are then used to assess improvement or deterioration in oxygenation. Ideally, the baseline value is compared with the PaO<sub>2</sub> obtained from an arterial blood sample collected concurrently to ensure the accuracy of the readings.

## **GENERAL CONSIDERATIONS**

Common diseases of the trachea and bronchi include canine infectious tracheobronchitis, canine chronic bronchitis, feline bronchitis, collapsing trachea, and allergic bronchitis. *Oslerus osleri* infection is an important consideration in young dogs.

Other diseases may involve the airways, either primarily or concurrently with pulmonary parenchymal disease. These diseases, such as viral, mycoplasmal, and bacterial infection; other parasitic infections; and neoplasia are discussed in Chapter 22. Feline bordetellosis can cause signs of bronchitis (e.g., cough) but is more often associated with signs of upper respiratory disease (see the section on feline upper respiratory infection, in Chapter 15) or bacterial pneumonia (see the section on bacterial pneumonia, in Chapter 22). Dogs with mild canine influenza virus infec-

tions have acute cough and often nasal discharge. This form of the disease is similar to canine infectious tracheobronchitis and is self-limiting. The severe form of the disease is characterized by pneumonia. Canine influenza is discussed in Chapter 22.

## CANINE INFECTIOUS TRACHEOBRONCHITIS

## Etiology

Canine infectious tracheobronchitis, or "kennel cough," is a highly contagious, acute disease that is localized in the airways. One or more infectious agents cause it, including canine adenovirus 2 (CAV2), parainfluenza virus (PIV), canine respiratory coronavirus and *Bordetella bronchiseptica*. *Bordetella* organisms infect ciliated respiratory epithelium (Fig. 21-1) and can decrease mucociliary clearance. Other organisms may become involved as secondary pathogens. In most dogs the disease is self-limiting, with resolution of clinical signs in approximately 2 weeks.

## **Clinical Features**

Affected dogs are first seen because of the sudden onset of a severe productive or nonproductive cough, which is often exacerbated by exercise, excitement, or the pressure of the collar on the neck. Palpating the trachea easily induces the cough. Gagging, retching, or nasal discharge can also occur. A recent history (i.e., within 2 weeks) of boarding, hospitalization, or exposure to a puppy or dog that has similar signs is common. Puppies recently obtained from pet stores, kennels, or shelters have often been exposed to the pathogens.

The majority of dogs with infectious tracheobronchitis are considered to have "uncomplicated," self-limiting disease and do not show signs of systemic illness. Therefore dogs showing respiratory distress, weight loss, persistent anorexia, or signs of involvement of other organ systems, such as diarrhea, chorioretinitis, or seizures, may have some other, more serious disease, such as canine distemper, severe canine

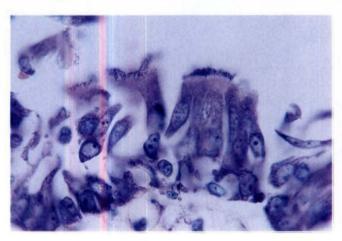

FIG 21-1
Photomicrograph of a tracheal biopsy from a dog infected with Bordetella bronchiseptica. The organisms are small basophilic rods that are visible along the ciliated border of the epithelial cells. (Giemsa stain courtesy D. Malarkey.)

influenza, or a mycotic infection. Although uncommon, serious respiratory complications can result from infectious tracheobronchitis. Secondary bacterial pneumonia can develop, particularly in puppies, immunocompromised dogs, and dogs that have preexisting lung abnormalities such as chronic bronchitis. Dogs with chronic airway disease or tracheal collapse can experience an acute, severe exacerbation of their chronic problems, and extended management may be necessary to resolve the signs associated with infection in these animals. *Bordetella* infection has been associated with canine chronic bronchitis.

#### Diagnosis

Uncomplicated cases of kennel cough are diagnosed on the basis of the presenting signs. However, differential diagnoses should also include the early presentation of a more serious disease and the mild form of canine influenza. Diagnostic testing is indicated for dogs with systemic, progressive, or unresolving signs. Tests to be considered include thoracic radiographs, a complete blood count (CBC), tracheal wash fluid analysis, and polymerase chain reaction (PCR) testing, paired serology, or other tests for canine influenza (see p. 302) and other respiratory pathogens. Tracheal wash fluid cytology shows acute inflammation, and bacterial culture of the fluid can be useful for identifying any bacteria involved in the disease. Concurrent antibiotic sensitivity information is helpful in selecting antibiotics.

#### **Treatment**

Uncomplicated infectious tracheobronchitis is a self-limiting disease. Rest for at least 7 days, specifically avoiding exercise and excitement, is indicated to minimize the continual irritation of the airways caused by excessive coughing. Cough suppressants are valuable for the same reason but should not be given if the cough is productive or if exudate is suspected to be accumulating in the lungs on the basis of auscultation

Common Cough Suppressants for Use in Dogs\*

AGENT	DOSAGE
Dextromethorphan <sup>†</sup>	1 to 2 mg/kg, q6-8h orally
Butorphanol	0.5 mg/kg, q6-12h orally
Hydrocodone bitartrate	0.25 mg/kg, q6-12h orally

\*Centrally acting cough suppressants are rarely, if ever, indicated for use in cats and can result in adverse reactions. The preceding dosages are for dogs only.

†Efficacy is questionable in dogs.

or thoracic radiograph findings. As discussed in Chapter 19 it is not always possible to recognize a productive cough in dogs. Therefore cough suppressants should be used judiciously to treat frequent or severe cough, allow for restful sleep, and prevent exhaustion.

A variety of cough suppressants can be used in dogs (Table 21-1). Dextromethorphan is available in over-the-counter preparations; however, it has questionable efficacy in dogs. Cold remedies with additional ingredients such as antihistamines and decongestants should be avoided. Pediatric liquid preparations are palatable for most dogs, and the alcohol contained in them may also have a mild tranquilizing effect. Narcotic cough suppressants are more likely to be effective. Butorphanol is available as a veterinary labeled product (Torbutrol, Fort Dodge Animal Health). Hydrocodone bitartrate is a potent alternative for dogs with refractory cough.

In theory, antibiotics are not indicated for most dogs with infectious tracheobronchitis for two reasons: (1) The disease is usually self-limiting and tends to resolve spontaneously, regardless of any specific treatment that is implemented, and (2) no antibiotic protocol has been proven to eliminate Bordetella organisms from the airways. In practice, however, antibiotics are often prescribed, and their use is justified because of the potential role of Bordetella in the disease. Fluoroquinolones have the advantage of reaching high concentrations in the airway secretions, but their use is ideally reserved for more serious infections. Other antibiotics that are effective against many Bordetella isolates include amoxicillin with clavulanate (20 to 25 mg/kg q8h), doxycycline (5 to 10 mg/kg q12h, followed by a bolus of water), and chloramphenicol (50 mg/kg q8h). Beta-lactam antibiotics do not generally reach therapeutic concentrations in airway secretions of healthy (not inflamed) subjects. If such an antibiotic is used for bronchial infections, the high end of the dosage range should be used and the drug administered every 8 hours. The ability of doxycycline to reach therapeutic concentration within the airways is questionable because in the dog it is highly protein bound, although the presence of inflammatory cells may increase locally available concentrations of the drug. Bacterial susceptibility data from tracheal wash fluid can be used to guide the selection of an

appropriate antibiotic. Antibiotics are administered for 5 days beyond the time the clinical signs resolve or for at least 14 days.

Administration of gentamicin by nebulization can be considered for refractory cases or in outbreaks of infection involving dogs housed together, although no controlled studies have been published. An early study by Bemis et al. (1997) showed that bacterial populations of Bordetella in the trachea and bronchi were reduced for up to 3 days after treatment with nebulized gentamicin but not orally administered antibiotics, and clinical signs were reduced. Note that the numbers of organisms returned to pretreatment values within 7 days. Some clinicians have since reported success in managing difficult cases and outbreaks with this treatment (Miller et al., 2003). The protocol used by Bemis et al. (1997) is 50 mg of gentamicin sulfate in 3 ml of sterile water, delivered by nebulizer and face mask (see Fig. 22-1) for 10 minutes every 12 hours for 3 days. Sterile technique must be maintained to keep from delivering additional bacteria to the airways. Nebulization of drugs has the potential to induce bronchospasms, so dogs should be carefully observed during the procedure. Pretreatment with bronchodilators should be considered, and additional bronchodilators (metered dose inhaler and/or injectable) should be at hand for use as needed.

Glucocorticoids should not be used. A field trial conducted by Thrusfield et al. (1991) failed to demonstrate any benefit of steroid therapy, either alone or in combination with antibiotics.

If clinical signs have not resolved within 2 weeks, further diagnostic evaluation is indicated. See Chapter 22 for the management of complicated cases of infectious tracheobronchitis with bacterial pneumonia.

#### **Prognosis**

The prognosis for recovery from uncomplicated infectious tracheobronchitis is excellent.

### **Prevention**

Canine infectious tracheobronchitis can be prevented by minimizing an animal's exposure to organisms and through vaccination programs. Excellent nutrition, routine deworming, and avoidance of stress improve the dog's ability to respond appropriately to infection without showing serious signs.

Bordetella may persist in the airways of dogs for up to 3 months after infection. To minimize exposure to Bordetella or respiratory viruses, dogs are kept isolated from puppies or dogs that have been recently boarded. Careful sanitation should be practiced in kenneling facilities. Caretakers should be instructed in the disinfection of cages, bowls, and runs, and anyone working with the dogs must wash their hands after handling each animal. Dogs should not be allowed to have face-to-face contact. Adequate air exchange and humidity control are necessary in rooms housing several dogs. Recommended goals are at least 10 to 15 air exchanges per hour and less than 50% humidity. An isolation area is essen-

tial for the housing of dogs with clinical signs of infectious tracheobronchitis.

Injectable and intranasal vaccines are available for the three major pathogens involved in canine infectious tracheobronchitis (i.e., CAV2, PIV, *B. bronchiseptica*). Injectable modified-live virus vaccines against CAV2 and PIV are adequate for most pet dogs. They are conveniently included in most combination distemper vaccines. Because maternal antibodies interfere with the response to the vaccines, puppies must be vaccinated every 2 to 4 weeks, beginning at 6 to 8 weeks of age and through 14 to 16 weeks of age. At least two vaccines must be given initially. For most healthy dogs, a booster is recommended after 1 year, followed by subsequent vaccinations every 3 years (see Chapter 94).

Dogs at high risk for disease, such as those in kennels where the disease is endemic or those that are frequently boarded, may benefit from vaccines incorporating B. bronchiseptica. These vaccines do not prevent infection but aim to decrease clinical signs if infection occurs. They may also reduce the duration of shedding of organisms after infection. A study by Ellis et al. (2001) indicated that both intranasal and parenteral Bordetella vaccines afford similar protection based on antibody titers, clinical signs, upper airway cultures, and histopathologic examination of tissues after exposure to organisms. The greatest benefit was achieved by administering both forms of vaccine sequentially at a 2-week interval. Unfortunately, the parenteral vaccine used in the study was a killed bacterin that is no longer available. The dogs in this study were vaccinated between 14 to 18 weeks of age. Also in experimental settings, protection against challenge following intranasal vaccination against B. bronchiseptica and PIV began by 72 hours after vaccination and persisted for at least 13 months (Gore et al., 2005; Jacobs et al., 2005). Intranasal Bordetella vaccines occasionally cause clinical signs, predominantly cough. The signs are generally self-limiting but are disturbing to most owners.

### CANINE CHRONIC BRONCHITIS

## Etiology

Canine chronic bronchitis is a disease syndrome defined as cough occurring on most days of 2 or more consecutive months in the past year in the absence of other active disease. Histologic changes of the airways are those of long-term inflammation and include fibrosis, epithelial hyperplasia, glandular hypertrophy, and inflammatory infiltrates. Some of these changes are irreversible. Excessive mucus is present within the airways, and small airway obstruction occurs. In people chronic bronchitis is strongly associated with smoking. It is presumed that canine chronic bronchitis is a consequence of a long-standing inflammatory process initiated by infection, allergy, or inhaled irritants or toxins. A continuing cycle of inflammation likely occurs as mucosal damage, mucus hypersecretion, and airway obstruction

impairs normal mucociliary clearance, and inflammatory mediators amplify the response to irritants and organisms.

#### **Clinical Features**

Chronic bronchitis occurs most often in middle-aged or older, small-breed dogs. Breeds commonly affected include Terriers, Poodles, and Cocker Spaniels. Small-breed dogs are also predisposed to the development of collapsing trachea and mitral insufficiency with left atrial enlargement causing compression of the mainstem bronchi. These causes for cough must be differentiated, and their contribution to the development of the current clinical features determined, for appropriate management to be implemented.

Dogs with chronic bronchitis are evaluated because of loud, harsh cough. Mucus hypersecretion is a component of the disease, but the cough may sound productive or nonproductive. The cough has usually progressed slowly over months to years, although clients usually report the initial onset as acute. There should be no systemic signs of illness such as anorexia or weight loss. As the disease progresses, exercise intolerance becomes evident; then incessant coughing or overt respiratory distress is seen.

Potential complications of chronic bronchitis include bacterial or mycoplasmal infection, tracheobronchomalacia (see p. 297), pulmonary hypertension (Chapter 22), and bronchiectasis. *Bronchiectasis* is the term for permanent dilation of the airways (Fig. 21-2; see also Fig. 20-4). Bronchiectasis can be present secondary to other causes of chronic airway inflammation, airway obstruction, and in association with certain congenital disorders such as ciliary dyskinesia (i.e., immotile cilia syndrome). Bronchiectasis caused by traction on the airways, rather than bronchial disease, can be seen with idiopathic pulmonary fibrosis. Generally, all the major airways are dilated in dogs with bronchiectasis, but occasionally it is localized. Recurrent bacterial infections and overt bacterial pneumonia are common complications in dogs with bronchiectasis.

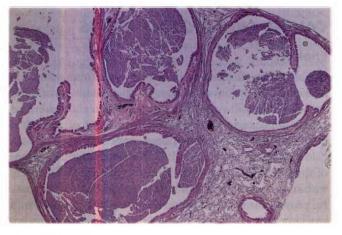

FIG 21-2
Photomicrograph of a lung biopsy from a dog with severe bronchiectasis. The airways are filled with exudate and are greatly dilated (H&E stain).

Dogs with chronic bronchitis are often brought to a veterinarian because of sudden exacerbation of signs. The change in signs may result from transient worsening of the chronic bronchitis, perhaps after a period of unusual excitement, stress, or exposure to irritants or allergens; from a secondary complication, such as bacterial infection; or from the development of a concurrent disease, such as left atrial enlargement and bronchial compression or heart failure (Box 21-1). In addition to obtaining a routine complete history, the client should be carefully questioned about the character of the cough and the progression of signs. Detailed information should be obtained regarding the following: environmental conditions, particularly exposure to smoke, other potential irritants and toxins, or allergens; exposure to infectious agents, such as boarding or exposure to puppies; and all previous and current medications and the response to treatment.

On physical examination, increased breath sounds, crackles, or occasionally wheezes are auscultated in animals with chronic bronchitis. End-expiratory clicks caused by mainstem bronchial or intrathoracic tracheal collapse may be heard in animals with advanced disease. A prominent or split second heart sound occurs in animals with secondary pulmonary hypertension. Dogs with respiratory distress (end-stage disease) characteristically show marked expiratory efforts because of the narrowing and collapse of the intrathoracic

large airways. The presence of a fever or other systemic signs is suggestive of other disease, such as bacterial pneumonia.

## **Diagnosis**

Canine chronic bronchitis is defined as a cough occurring on most days of 2 or more consecutive months in the past year *in the absence of other active disease*. Therefore chronic bronchitis is diagnosed on the basis of not only clinical signs but also the elimination of other diseases from the list of differential diagnoses (see Box 21-1). The possibility of secondary disease complicates this simple definition.

A bronchial pattern with increased interstitial markings is typically seen on thoracic radiographs, but changes are often mild and difficult to distinguish from clinically insignificant changes associated with aging. In a study by Mantis et al. (1998), thoracic radiographs had a sensitivity of 50% to 65% for the diagnosis of chronic bronchitis. Thoracic radiographs are most useful for ruling out other active disease and identifying concurrent or secondary disease.

Tracheal wash or bronchoalveolar lavage (BAL) fluid should be collected at the time of the initial presentation and after a persistent exacerbation of signs. Neutrophilic or mixed inflammation and increased amounts of mucus are usually present. The finding of degenerative neutrophils indicates the possibility of a bacterial infection. Although not a specific finding, airway eosinophilia is suggestive of a hypersensitivity reaction, as can occur with allergy, parasitism, or heartworm disease. Slides should be carefully examined for organisms. Bacterial cultures are performed and the results interpreted as discussed in Chapter 20. Although the role of *Mycoplasma* infections in these cases is not well understood, *Mycoplasma* cultures are also considered.

Bronchoscopy, with specimen collection, is performed in selected cases, primarily to help rule out other diseases. The maximal benefit of bronchoscopy is obtained early in the course of disease, before severe permanent damage has occurred and while the risk of the procedure is minimal. Gross abnormalities visualized by bronchoscopy include an increased amount of mucus, roughened mucosa, and hyperemia. Major airways may collapse during expiration as a result of weakened walls (Fig. 21-3), and polypoid mucosal proliferation may be present. Bronchial dilatation is seen in animals with bronchiectasis.

Further diagnostic procedures are indicated to rule out other potential causes of chronic cough, and the selection of these depends on the presenting signs and the results of the previously discussed diagnostic tests. Diagnostic tests to be considered include heartworm tests, fecal examinations for pulmonary parasites, echocardiography, and systemic evaluation (i.e., CBC, serum biochemical panel, urinalysis). Echocardiography may reveal evidence of secondary pulmonary hypertension, including right heart enlargement (i.e., cor pulmonale).

Ciliary dyskinesia, in which ciliary motion is abnormal, is uncommon but should be considered in young dogs with bronchiectasis or recurrent bacterial infection. Abnormalities exist in all ciliated tissues, and situs inversus (i.e., lateral

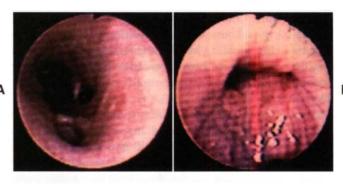

FIG 21-3

transposition of the abdominal and thoracic organs, such that left-sided structures are found on the right and vice versa) is seen in 50% of such dogs. Dextrocardia occurring in association with chronic bronchitis is extremely suggestive of this disease. Sperm motility can be evaluated in intact male dogs. The finding of normal sperm motility rules out a diagnosis of ciliary dyskinesia. The disease is diagnosed on the basis of the rate at which radioisotopes deposited at the carina are cleared and the findings from electron microscopic examination of bronchial biopsy, nasal biopsy, or sperm specimens.

#### **Treatment**

Chronic bronchitis is managed symptomatically, with specific treatment possible only for concurrent or complicating diseases that are identified. Each dog with chronic bronchitis is presented at a different stage of the disease, with or without concurrent or secondary cardiopulmonary disease (see Box 21-1). Hence each dog must be managed individually. Ideally, medications are initiated one at a time to assess the most effective combination. It will likely be necessary to modify treatment over time.

## **GENERAL MANAGEMENT**

Exacerbating factors, either possible or proven, are avoided. Potential allergens are considered in dogs with eosinophilic inflammation and trial elimination pursued (see the section on allergic bronchitis, p. 299). Exposure to irritants such as smoke (from tobacco or fireplace) and perfumed products should be avoided in all dogs. Motivated clients can take steps to improve the air quality in their home, such as carpet, furniture, and drapery cleaning; cleaning of the furnace and the frequent replacement of air filters; and the use of an air cleaner. The American Lung Association has a useful Web site with nonproprietary recommendations for improving indoor air quality (www.lungusa.org ). Excitement or stress can cause an acute worsening of signs in some animals, and short-term tranquilization with acepromazine or sedation with phenobarbital can be helpful in relieving the signs.

It is normal for flora from the oropharynx to be aspirated into the airways. Routine dental prophylaxis and teeth brushing will help maintain a healthy oral flora and may decrease any contributions of normal aspiration to ongoing airway inflammation in these patients with reduced mucociliary clearance.

Airway hydration should be maintained to facilitate mucociliary clearance. Adequate airway hydration is best achieved by maintaining systemic hydration. Therefore diuretic therapy is not recommended in these patients. For severely affected dogs, placing the animal in a steamy bathroom or in a room with a vaporizer daily may provide symptomatic relief, although the moisture does not penetrate very deeply into the airways. Nebulization of saline will allow moisture to go more deeply in the lungs. This technique is discussed further in the section on bacterial pneumonia in Chapter 22.

Patients that are overweight and/or unfit may benefit from weight loss (Chapter 54) and exercise. Exercise should be tailored to the dog's current fitness level and degree of pulmonary dysfunction to keep from causing excessive respiratory efforts or even death. Observing the dog during specific exercise, such as a short walk, while in the client's presence may be necessary to make initial recommendations. Instructing clients in the measurement of respiratory rate, observation of mucous membrane color, and signs of increased respiratory effort will improve their ability to assess their dog's status during exercise.

## DRUG THERAPIES

Medications to control clinical signs include bronchodilators, glucocorticoids, and cough suppressants.

Theophylline, a methylxanthine bronchodilator, has been used for years for the treatment of chronic bronchitis in people and dogs. This drug became unpopular with physicians when newer bronchodilators with fewer side effects became available. However, recent research in people suggests that theophylline is effective in treating the underlying inflammation of chronic bronchitis, even at concentrations below those resulting in bronchodilation (hence, reducing side effects), and that the antiinflammatory effects may be synergistic with those of glucocorticoids. Theophylline may also improve mucociliary clearance, decrease fatigue of respiratory muscles, and inhibit the release of mast cell mediators of inflammation. The potential beneficial effects of theophylline beyond bronchodilation may be of particular importance in dogs because their airways are not as reactive (i.e., likely to bronchospasm) as those of cats and people. However, theophylline alone is rarely sufficient to control the clinical signs of chronic bronchitis.

Other advantages of theophylline are the availability of long-acting preparations that can be administered twice daily to dogs and the fact that plasma concentrations of drug can be easily measured by commercial diagnostic laboratories. A disadvantage of theophylline is that other drugs, such as fluoroquinolones and chloramphenicol, can delay its clearance and cause signs of theophylline toxicity if the

dosage is not reduced by one third to one half. Potential adverse effects include gastrointestinal signs, cardiac arrhythmias, nervousness, and seizures. Serious adverse effects are extremely rare at therapeutic concentrations.

Variability in sustained plasma concentrations has been found for different long-acting theophylline products. Dosage recommendations are currently available for a generic product from a specific manufacturer (Box 21-2). If beneficial effects are not seen, the patient is predisposed to adverse effects, or adverse effects occur, plasma theophylline concentrations should be measured. Therapeutic peak concentrations for bronchodilation, based on data from people, are 5 to 20 µg/ml. Plasma is collected during peak concentrations, generally 4 to 5 hours after administration of a long-acting product or 1.5 to 2 hours after administration of immediate release products. Measurement of concentrations immediately before the next scheduled dose might provide useful information concerning duration of therapeutic concentrations.

Theophylline and related drugs that are not long acting are useful in specific circumstances but must be administered three times daily (see Box 21-2). Palatable elixirs of

Terbutaline

Cat: 1/8-1/4 of 2.5 mg tablet/cat orally q12h; or 0.01 mg/kg subcutaneously; can repeat once

Dog: 1.25-5 mg/dog orally q8-12h

Albuterol

Cat and Dog: 20-50 µg/kg orally q8-12h (0.02-0.05 mg/kg), beginning with lower dose.

\*Canine dosage for these products from Inwood Laboratories from Bach JF et al: Evaluation of the bioavailability and pharmacokinetics of two extended-release theophylline formulations in dogs, J Am Vet Med Assoc 224:1113, 2004. Feline dosage from Guenther-Yenke CL et al: Pharmacokinetics of an extended-release theophylline product in cats. J Am Vet Med Assoc 231:900, 2007. Monitoring of plasma concentrations is recommended in patients at risk for or with signs of toxicity and in patients that fail to respond to treatment.

theophylline derivatives (e.g., oxtriphylline) are convenient for administration to toy breeds. Therapeutic blood concentrations are reached more quickly after the administration of liquids, or tablets or capsules that are not long acting.

Sympathomimetic drugs are preferred by some clinicians as bronchodilators (see Box 21-2). Terbutaline and albuterol are selective for  $\beta_2$ -adrenergic receptors, lessening their cardiac effects. Potential adverse effects include nervousness, tremors, hypotension, and tachycardia. The clinical use of bronchodilators delivered by metered-dose inhaler, such as albuterol and ipatropium (a parasympatholytic), has not been reported in dogs with chronic bronchitis.

Glucocorticoids are often effective in controlling the signs of chronic bronchitis and may slow the development of permanent airway damage by decreasing inflammation. They may be particularly helpful in dogs with eosinophilic airway inflammation. Potential negative effects include an increased susceptibility to infection in dogs already impaired by decreased airway clearance; a tendency toward obesity, hepatomegaly, and muscle weakness that may adversely affect ventilation; and pulmonary thromboembolism. Therefore short-acting products are used, the dose is tapered to the lowest effective one (when possible, 0.5 mg/kg q48h or less), and the drug is discontinued if no beneficial effect is seen. Prednisone is initially given at a dose of 0.5 to 1.0 mg/kg every 12 hours, with a positive response expected within 1 week.

Dogs that require relatively high dosages of prednisone, have unacceptable adverse effects, or have conditions for which glucocorticoids are relatively contraindicated (e.g., diabetes mellitus) may benefit from local treatment with metered-dose inhalers. This route of administration is discussed in more detail later in this chapter, in the section on feline bronchitis (p. 295).

Cough suppressants are used cautiously because cough is an important mechanism to clear airway secretions. In some dogs, however, the cough is incessant and exhausting, or ineffective because of marked tracheobronchomalacia and airway collapse. Cough suppressants can provide significant relief in such animals and may even facilitate ventilation and decrease anxiety.

Although the doses given in Table 21-1 are the ones that provide prolonged effectiveness, less frequent administration (i.e., only during times of the day when coughing is most severe) may preserve some beneficial effect of cough. For dogs with severe cough, hydrocodone may provide the greatest relief.

#### MANAGEMENT OF COMPLICATIONS

Antibiotics are often prescribed for dogs with chronic bronchitis. If possible, confirmation of infection and antibiotic sensitivity information should be obtained by culture of an airway specimen (e.g., tracheal wash fluid). Because cough in dogs with chronic bronchitis often waxes and wanes in severity, it is difficult to make a diagnosis of infection on the basis of the patient's response to therapy. Furthermore,

organisms involved in bronchial infections generally originate from the oropharynx. They are frequently gramnegative with unpredictable antibiotic sensitivity patterns. The role of *Mycoplasma* organisms in canine chronic bronchitis is not well understood. They may be an incidental finding or pathogenic. Ideally, antibiotic selection is based on results of culture. Antibiotics that are generally effective against *Mycoplasma* include doxycycline, azithromycin, chloramphenicol, and fluoroquinolones.

In addition to the susceptibility of identified organisms, the ability of selected antibiotics to penetrate the airway secretions to the site of infection should be considered when selecting an antibiotic. Antibiotics that are likely to reach concentrations effective against susceptible organisms include chloramphenicol, fluoroquinolones, azithromycin, and possibly amoxicillin with clavulanate. Beta-lactam antibiotics do not generally reach therapeutic concentrations in airway secretions of healthy (not inflamed) subjects. If used for bronchial infections, the high end of the dosage range should be used and the drug administered every 8 hours (20 to 25 mg/kg q8h). Doxycycline has often been recommended because Mycoplasma and many Bordetella isolates are susceptible to this drug. However, the ability of doxycycline to reach therapeutic concentration within the airways is questionable because in the dog it is highly protein bound, although the presence of inflammatory cells may increase locally available concentrations of the drug. It is preferable to reserve fluoroquinolones for serious infections.

If an antibiotic is effective, a positive response is generally seen within 1 week. Treatment is then continued for at least 1 week beyond the time when the clinical signs stabilize because complete resolution is unlikely in these animals. Antibiotic treatment usually is necessary for 3 to 4 weeks. Even longer treatment may be necessary in some cases, particularly if bronchiectasis or overt pneumonia is present. The use of antibiotics for the treatment of respiratory tract infections is also discussed in the section on canine infectious tracheobronchitis in this chapter (p. 285) and in the section on bacterial pneumonia in Chapter 22.

Tracheobronchomalacia is discussed on p. 297, and pulmonary hypertension is discussed in Chapter 22.

#### **Prognosis**

Canine chronic bronchitis cannot be completely cured. The prognosis for the control of signs and a satisfactory quality of life in animals is good if the owners are conscientious about performing the medical management aspects of care, are willing to adjust treatment over time, and treat secondary problems as they occur.

## **FELINE BRONCHITIS (IDIOPATHIC)**

#### Etiology

Cats with respiratory disease of many etiologies present with signs of bronchitis or asthma. Cat airways are much more reactive, prone to bronchoconstriction, than dogs. The common presenting signs of bronchitis (i.e., cough, wheezing, and/or respiratory distress) can occur in cats with diseases as varied as lung parasites, heartworm disease, allergic bronchitis, bacterial or viral bronchitis, toxoplasmosis, idiopathic pulmonary fibrosis, carcinoma, and aspiration pneumonia (Table 21-2). Veterinarians often assume that cats with presenting signs of bronchitis or asthma have idiopathic disease because in most cats an underlying etiology cannot be found. However, as with canine chronic bronchitis, a diagnosis of idiopathic feline bronchitis can be made only by ruling out other active disease. Care should be taken when using the terms feline bronchitis or feline asthma to distinguish between a presentation consistent with bronchitis in a broad sense and a clinical diagnosis of idiopathic disease. Cats with idiopathic bronchitis often have some degree of airway eosinophilia, typical of an allergic reaction. This author prefers to reserve the diagnosis of allergic bronchitis to patients who respond dramatically to the elimination of a suspected allergen (see p. 299).

A wide variety of pathologic processes can affect individual cats with idiopathic bronchitis. Clinically, the range in the severity of signs and the response to therapy shows this diversity. Different combinations of factors that result in small airway obstruction, a consistent feature of feline bronchial disease, are present in each animal (Box 21-3). Some of these factors are reversible (e.g., bronchospasm, inflammation), and some are permanent (e.g., fibrosis, emphysema). The classification proposed by Moise et al. (1989), which was formulated on the basis of similar pathologic processes that occur in people, is recommended as a way to better define bronchial disease in individual cats for the purpose of treatment recommendations and prognostication (Box 21-4). A cat can also have more than one type of bronchitis. Although it is not always possible to absolutely determine the type or types of bronchial disease present without sophisticated pulmonary function testing, routine clinical data (i.e., history and physical examination findings, thoracic radiographs, analysis of airway specimens, progression of signs) can be used to classify the disease in most cats.

Differential Diagnoses (Etiologic) for Cats with Presenting Signs of Bronchitis

#### **DIAGNOSIS**

## DISTINGUISHING FEATURES COMPARED WITH IDIOPATHIC FELINE BRONCHITIS

Allergic bronchitis

Pulmonary parasites (Aelurostrongylus abstrusus; Capillaria aerophila; Paragonimus kellicotti) Heartworm disease

Bacterial bronchitis

Mycoplasmal bronchitis

Idiopathic pulmonary fibrosis

Carcinoma

Toxoplasmosis

Aspiration pneumonia

Idiopathic feline bronchitis

BAL, bronchoalveolar lavage.

Dramatic clinical response to elimination of suspected allergen(s) from environment or diet.

Thoracic radiographs may have a nodular pattern; Larvae (*Aelurostongylus*) or eggs identified in tracheal wash or BAL fluid or in the feces. See Chapter 20 for appropriate procedures for fecal testing.

Pulmonary artery enlargement may be present on thoracic radiographs; positive heartworm antigen test or identification of adult worm(s) on echocardiography (see Chapter 10).

Intracellular bacteria in tracheal wash or BAL fluid and significant growth on culture (see Chapter 20).

Growth of Mycoplasma on specific culture of tracheal wash or BAL fluid (presence may indicate primary infection, secondary infection, or be incidental).

Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis; diagnosis requires lung biopsy (see Chapter 22).

Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis. Cytologic or histologic identification of malignant cells in tracheal wash or BAL fluid, lung aspirates, or lung biopsy. Histologic confirmation is ideal.

Systemic signs usually present (fever, anorexia, depression). Radiographs may show more severe infiltrates than expected in cats with idiopathic bronchitis, possibly with a nodular pattern. Diagnosis is confirmed by identification of organisms (tachyzoites) in tracheal wash or BAL fluid. Rising serum antibody titers or elevated IgM concentrations are supportive of the diagnosis (see Chapter 99).

Unusual in cats. History supportive of a predisposing event or condition. Radiographs typically show an alveolar pattern, worse in the dependent (cranial and middle) lung lobes. Neutrophilic inflammation, usually with bacteria, in tracheal wash fluid.

Elimination of other diseases from the differential diagnoses.

BOX 21-3

Factors that Can Contribute to Small Airway Obstruction in Cats with Bronchial Disease

Bronchoconstriction
Bronchial smooth muscle hypertrophy
Increased mucus production
Decreased mucus clearance
Inflammatory exudate in airway lumens
Inflammatory infiltrate in airway walls
Epithelial hyperplasia
Glandular hypertrophy
Fibrosis
Emphysema

BOX 21-4

Classification of Feline Bronchial Disease

#### **Bronchial Asthma**

Predominant feature: reversible airway obstruction primarily resulting from bronchoconstriction

Other common features: hypertrophy of smooth muscle, increased mucus production, eosinophilic inflammation

#### **Acute Bronchitis**

Predominant feature: reversible airway inflammation of short duration (<1-3 months)

Other common features: increased mucus production, neutrophilic or macrophagic inflammation

#### **Chronic Bronchitis**

Predominant feature: chronic airway inflammation (>2-3 months) resulting in irreversible damage (e.g., fibrosis)
Other common features: increased mucus production; neutrophilic, eosinophilic, or mixed inflammation; isolation of bacteria or Mycoplasma organisms causing infection or as nonpathogenic inhabitants; concurrent bronchial asthma

#### Emphysema

Predominant feature: destruction of bronchiolar and alveolar walls resulting in enlarged peripheral air spaces Other common features: cavitary lesions (bullae); result of or concurrent with chronic bronchitis

Adapted from Moise NS et al: Bronchopulmonary disease. In Sherding RG, editor: *The cat: diseases and clinical management,* New York, 1989, Churchill Livingstone.

## **Clinical Features**

Idiopathic bronchitis can develop in cats of any age, although it most commonly develops in young adult and middle-aged animals. The major clinical feature is cough or episodic respiratory distress or both. The owners may report audible wheezing during an episode. The signs are often slowly progressive. Weight loss, anorexia, depression, or other systemic

signs are not present. If systemic signs are identified, another diagnosis should be aggressively pursued.

Owners should be carefully questioned regarding an association with exposure to potential allergens or irritants. Irritants in the environment can cause worsening of signs of bronchitis regardless of the underlying etiology. Environmental considerations include exposure to new litter (usually perfumed), cigarette or fireplace smoke, carpet cleaners, and household items containing perfumes such as deodorant or hair spray. Clients should also be questioned about whether there has been any recent remodeling or any other change in the cat's environment. Seasonal exacerbations are suggestive of potential allergen exposure.

Physical examination abnormalities result from small airway obstruction. Cats that are in distress show tachypnea. Typically the increased respiratory efforts are more pronounced during expiration, and auscultation reveals expiratory wheezes. Crackles are occasionally present. In some patients in distress, hyperinflation of the lungs due to air trapping may result in increased inspiratory efforts and decreased lung sounds. Physical examination findings may be unremarkable between episodes.

## Diagnosis

A diagnosis of idiopathic feline bronchitis is made on the basis of typical historical, physical examination, and thoracic radiographic findings and the elimination of other possible differential diagnoses (see Table 21-2). A thorough search for other diagnoses is highly recommended, even though a specific diagnosis is not commonly found, because identifying an etiology for the clinical signs may allow for specific treatment and even cure of an individual cat. Factors to consider when developing a diagnostic plan include the clinical condition of the cat and the client's tolerance for expense and risk. Cats that are in respiratory distress or are otherwise in critical condition should not undergo any stressful testing until their condition has stabilized. Sufficiently stable cats that have any indication of a diagnosis other than idiopathic disease on the basis of presenting signs and thoracic radiographs or any subsequent test results require a thorough evaluation. Certain tests are completely safe, such as fecal testing for pulmonary parasites, and their inclusion in the diagnostic plan is largely based on financial considerations. In most cats with signs of bronchitis, collection of tracheal wash fluid for cytology and culture and tests for pulmonary parasitism and heartworm disease are recommended.

A CBC is often performed as a routine screening test. Cats with idiopathic bronchitis are often thought to have peripheral eosinophilia. However, this finding is neither specific nor sensitive and cannot be used to rule out or definitively diagnose feline bronchitis.

Thoracic radiographs from cats with bronchitis generally show a bronchial pattern (see Fig. 20-3). Increased reticular interstitial markings and patchy alveolar opacities may also be present. The lungs may be seen to be overinflated as a result of the trapping of air, and occasionally collapse (i.e., atelectasis) of the right middle lung lobe is seen (see Fig.

20-9). However, because clinical signs can precede radiographic changes and because radiographs cannot detect mild airway changes, thoracic radiographs may be normal in cats with bronchitis. Radiographs are also scrutinized for signs of specific diseases (see Table 21-2).

The tracheal wash or BAL fluid cytologic findings are generally representative of the airway inflammation and consist of increased numbers of inflammatory cells and an increased amount of mucus. Inflammation can be eosinophilic, neutrophilic, or mixed. Although not a specific finding, eosinophilic inflammation is suggestive of a hypersensitivity response to allergens or parasites. Neutrophils should be examined for signs of the degeneration suggestive of bacterial infection. Slides should be carefully scrutinized for the presence of organisms, particularly bacteria and parasitic larvae or ova. Fluid should be cultured for bacteria, although it is important to note that the growth of organisms may or may not indicate the existence of true infection (see Chapter 20). Cultures for *Mycoplasma* spp. may also be helpful.

Testing for heartworm disease is described in Chapter 10. Multiple fecal examinations using special concentrating techniques are performed to identify pulmonary parasites, particularly in young cats and cats with airway eosinophilia (see Chapter 20). Other tests may be indicated for individual cats.

#### **Treatment**

### **EMERGENCY STABILIZATION**

The condition of cats in acute respiratory distress should be stabilized before diagnostic tests are performed. Successful treatment includes administration of a bronchodilator, rapid-acting glucocorticoids, and oxygen supplementation. Terbutaline can be administered subcutaneously, a route that avoids additional patient stress (see Box 21-2). Prednisolone sodium succinate is the recommended glucocorticoid for a life-threatening crisis (up to 10 mg/kg, administered intravenously). If intravenous administration is too stressful, the drug can be given intramuscularly. Alternatively, dexamethasone sodium phosphate (up to 2 mg/kg, administered intravenously) can be given. After the drugs are administered, the cat is placed in a cool, stress-free, oxygen-enriched environment. If additional bronchodilation is desired, albuterol can be administered by nebulization or metered-dose inhaler (MDI). Administration of drugs by MDI is described later in this section. (See Chapter 26 for further discussion of cats with respiratory distress.)

### **ENVIRONMENT**

The potential influence of the environment on clinical signs should be investigated. Allergic bronchitis is diagnosed through the elimination of potential allergens from the environment (see the section on allergic bronchitis). However, even cats with idiopathic bronchitis can benefit from improvement in indoor air quality through the reduction of irritants or unidentified allergens. Potential sources of allergens or irritants are determined through careful

owner questioning as described in the section on clinical features. Smoke can often aggravate signs because of its local irritating effects. The effect of litter perfumes can be evaluated by replacing the litter with sandbox sand or plain clay litter. Indoor cats may show improvement in response to measures taken to decrease the level of dusts, molds, and mildew in the home. Such measures include carpet, furniture, and drapery cleaning; cleaning of the furnace and the frequent replacement of air filters; and the use of an air cleaner. The American Lung Association has a useful website with nonproprietary recommendations for improving indoor air quality (www.lungusa.org). Any beneficial response to an environmental change is usually seen within 1 to 2 weeks.

#### **GLUCOCORTICOIDS**

Therapy with glucocorticoids, with or without bronchodilators, is necessary for most cats with idiopathic bronchitis. Results can be dramatic. However, drug therapy can interfere with environmental testing; therefore the ability of the animal to tolerate a delay in the start of drug therapy must be assessed on an animal-by-animal basis. Glucocorticoids can relieve the clinical signs in most cats and may protect the airways from the detrimental effects of chronic inflammation. Short-acting products such as prednisolone are recommended because the dose can be tapered to the lowest effective amount. Anecdotal experience and a preliminary study suggest that prednisolone may be more effective in cats than prednisone (Graham-Mize et al., 2004). A dose of 0.5 to 1 mg/kg is administered every 12 hours initially, with the dose doubled if signs are not controlled within 1 week. Once the signs are well controlled, the dose is tapered. A reasonable goal is to administer 0.5 mg/kg or less every other day. Outdoor cats that cannot be treated frequently can be administered depot steroid products, such as methylprednisolone acetate (10 mg/cat intramuscularly may be effective for up to 4 weeks).

Glucocorticoids, such as fluticasone propionate (Flovent, GlaxoSmithKline), can also be administered locally to the airways by MDI, as is routine for treating asthma in people. The advantages are minimal systemic side effects and relative ease of administration in some cats compared with pilling. To date, however, it is still not known how much drug is deposited in the lower airways, how much remains in the oral and nasal cavities, and how much is absorbed systemically in cats. Theoretical concerns about the oronasal deposition of the potent glucocorticoid in cats, compared with people, include the high incidence of periodontal disease and latent herpesvirus infections and the inability to effectively rinse the mouth with water after use. Local dermatitis because of mites, dermatophytes, or bacteria can occur. However, some veterinarians have been using glucocorticoid MDIs to treat idiopathic feline bronchitis for many years without frequent, obvious adverse effects.

This author prefers to obtain a clinical remission of signs using orally administered drug first, except in cats with relative contraindications for systemic glucocorticoid therapy, such as diabetes mellitus. Cats that require a relatively low

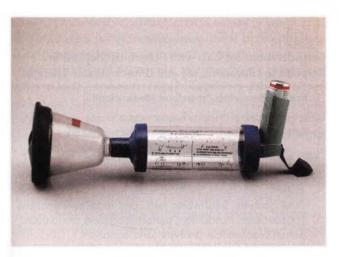

FIG 21-4
Apparatus for administering drugs by metered dose inhaler (MDI) to cats consisting of an anesthetic mask, spacer (OptiChamber, Respironics, Inc., Pittsburgh, Pa.), and MDI (Ventolin, GlaxoSmithKline, Research Triangle Park, N.C.).

dose of oral glucocorticoids to control clinical signs, have no noticeable adverse effects, and can be pilled without difficulty are often well maintained with oral therapy. Otherwise, once signs are in remission, treatment by MDI is initiated and the dosage of oral prednisolone gradually reduced.

A spacer must be used for effectively administering drugs by MDI to cats, and the airflow generated by the cat must be sufficient to activate the spacer valve. Padrid (2000) has found the OptiChamber (Respironics, Inc) to be effective (Fig. 21-4). A small anesthetic mask, with rubber diaphragm, is attached to the spacer. Widening of the adapter of the anesthetic mask that is inserted into the spacer is necessary to create a snug fit. This is achieved by wrapping adhesive tape around the adapter. Alternatively, a mask with spacer specifically designed for use in cats is available (Aerokat, Trudell Medical International). The cat is allowed to rest comfortably on a table or in the client's lap. The client places his or her arms on either side of the cat or gently steadies the cat's neck and head to provide restraint (Fig. 21-5). The MDI, attached to the spacer, is actuated (i.e., pressed) twice. The mask is placed immediately on the cat's face, covering the mouth and nose completely, and is held in place while the cat takes 7 to 10 breaths, inhaling the drug into its airways.

The following treatment schedule has been recommended (Padrid, 2000): Cats with mild daily symptoms should receive 220 Lg of fluticasone propionate by MDI twice daily and albuterol by MDI as needed. The maximal effect of fluticasone is not expected until 7 to 10 days of treatment. Cats with moderate daily symptoms should receive treatments with MDI as described for mild symptoms; in addition, prednisolone is administered orally for 10 days (1 mg/kg every 12 hours for 5 days, then every 24 hours for 5 days). For cats with severe symptoms, dexamethasone is administered once (2 mg/kg, intravenously), albuterol is adminis-

FIG 21-5
Administering drugs by metered-dose inhaler (MDI) to a cat.
The mask and chamber apparatus is the Aerokat (Trudell Medical International, London, Ontario, Canada).

tered by MDI every 30 minutes for up to 4 hours, and oxygen is administered. Once stabilized, these cats are prescribed 220  $\mu$ g of fluticasone propionate by MDI every 12 hours and albuterol by MDI every 6 hours as needed. Oral prednisolone is administered as needed.

#### **BRONCHODILATORS**

Cats that require relatively large amounts of glucocorticoids to control clinical signs, react unfavorably to glucocorticoid therapy, or suffer from periodic exacerbations of signs can benefit from bronchodilator therapy. Recommended doses of these drugs are listed in Box 21-2.

This author prefers to use theophylline because it is effective and inexpensive and can be given to cats once daily; moreover, the plasma concentrations can be easily measured for the monitoring of difficult cases. Additional properties of theophylline, potential drug interactions, and adverse effects are described in the section on canine chronic bronchitis (p. 290).

The pharmacokinetics of theophylline products are different in cats compared with dogs, resulting in different dosages (see Box 21-2). Variability in sustained plasma concentrations in both species has been found for different longacting theophylline products. Dosage recommendations are currently available for a generic product from a specific manufacturer (Box 21-2). However, the individual metabolism of all of the methylxanthines is variable. If beneficial effects are not seen, the patient is predisposed to adverse effects, or adverse effects occur, plasma theophylline concentrations should be measured. Therapeutic peak concentrations, based on data from human subjects, are 5 to 20 g/ml. Plasma for the determination of these concentrations should be collected 12 hours after the evening dosing of the longacting products and 2 hours after short-acting products. Measurement of concentrations immediately before the next scheduled dose might provide useful information concerning duration of therapeutic concentrations.

Sympathomimetic drugs can also be effective bronchodilators. Terbutaline is selective for  $\beta_2$ -adrenergic receptors, lessening its cardiac effects. Potential adverse effects include nervousness, tremors, hypotension, and tachycardia. It can be administered subcutaneously for the treatment of respiratory emergencies; it can also be administered orally. Note that the recommended oral dose for cats (one eighth to one fourth of a 2.5-mg tablet; see Box 21-2) is lower than the commonly cited dose of 1.25 mg/cat. The subcutaneous dose is lower still: 0.01 mg/kg, repeated once in 5 to 10 minutes if necessary.

Bronchodilators can be administered to cats by MDI for the immediate treatment of acute respiratory distress (asthma attack). Cats with idiopathic bronchitis are routinely prescribed an albuterol MDI, spacer, and mask (see the section on glucocorticoids for details) to be kept at home for emergencies.

#### OTHER POTENTIAL TREATMENTS

A therapeutic trial with an antibiotic effective against *Mycoplasma* is considered because of the difficulty in documenting infection with this organism. Either doxycycline (5 to 10 mg/kg q12h) or chloramphenicol (10 to 15 mg/kg q12h) is administered for 14 days. For cats that are difficult to medicate, azithromycin (5 to 10 mg/kg q24h for 3 days, then q72h) can be tried. Remember that administration of doxycycline should always be followed with a bolus of water to minimize the incidence of esophageal stricture.

Antihistamines are not recommended for treating feline bronchitis because histamine in some cats produces bronchodilation. However, work done by Padrid et al. (1995) has shown that the serotonin antagonist, cyproheptadine, has a bronchodilatory effect *in vitro*. A dose of 2 mg/cat orally every 12 hours can be tried in cats with signs that cannot be controlled with routine bronchodilator and glucocorticoid therapy. This treatment is not consistently effective.

Much interest has been shown among clients and veterinarians in the use of oral leukotriene inhibitors in cats (e.g., Accolate, Singulair, and Zyflo). However, the clinician should be aware that in people, leukotriene inhibitors are *less* effective in the management of asthma than glucocorticoids, and they are not used in the emergency management of the disease or for refractory cases. Their advantage for people lies in decreased side effects, compared with glucocorticoids, and ease of administration. To date, toxicity studies have not been performed on these drugs in cats. Furthermore, several preliminary studies suggest that leukotriene inhibition in cats would not be expected to have efficacy comparable to that in people. Therefore their routine use in cats is not currently advocated. Further investigation into their potential role in treating feline bronchitis is certainly indicated.

## FAILURE TO RESPOND

The clinician should ask himself or herself the questions listed in Box 21-5 if cats fail to respond to glucocorticoid and bronchodilator therapy or if exacerbation of signs occurs during chronic treatment.

BOX 21-5

Considerations for Cats with Bronchitis that Fail to Respond to Glucocorticoid and Bronchodilator Therapy

#### Is the Cat Receiving Prescribed Medication?

Measure plasma theophylline concentrations. Initiate trial therapy with repositol glucocorticoids.

## Was an Underlying Disease Missed on Initial Evaluation?

Repeat diagnostic evaluation, including complete history for potential allergens, thoracic radiographs, tracheal wash fluid analysis, heartworm tests, and fecal examinations for parasites. In addition, perform complete blood count, serum biochemical analysis, and urinalysis.

Initiate trial therapy with anti-Mycoplasma drug.
Initiate trial environmental manipulations to minimize potential allergen and irritant exposure.

#### Has a Complicating Disease Developed?

Repeat diagnostic evaluation as described in the preceding sections.

## **Prognosis**

The prognosis for the control of clinical signs of idiopathic feline bronchitis is good for most cats, particularly if extensive permanent damage has not yet occurred. Complete cure is unlikely, and most cats require continued medication. Cats that have severe, acute asthmatic attacks are at risk for sudden death. Cats with persistent, untreated airway inflammation can develop the permanent changes of chronic bronchitis and emphysema.

## COLLAPSING TRACHEA AND TRACHEOBRONCHOMALACIA

## Etiology

The normal trachea is seen to be circular on cross section (see Fig. 21-8, *B*, and Fig. 20-27, *A*). An open lumen is maintained during all phases of quiet respiration by the cartilaginous tracheal rings, which are connected by fibroelastic annular ligaments to maintain flexibility, thereby allowing movement of the neck without compromising the airway. The cartilaginous rings are incomplete dorsally. The dorsal tracheal membrane, consisting of the longitudinal tracheal muscle and connective tissue, completes the rings. The term *tracheal collapse* refers to the narrowing of the tracheal lumen resulting from weakening of the cartilaginous rings, a redundancy of the dorsal tracheal membrane, or both. The condition can affect the extrathoracic trachea, the intrathoracic trachea, or both.

A credible theory of the pathogenesis of tracheal collapse is that certain dogs are predisposed to collapse because of inherent abnormalities in their cartilage but are initially asymptomatic. An exacerbating problem develops that

results in increased respiratory efforts, airway inflammation, and/or cough. Changes in intrathoracic and airway pressures during increased respiratory efforts or cough likely contribute to narrowing of the trachea, and the chronic presence of inflammatory mediators (e.g., collagenases and proteases) within the trachea likely further weaken its structure. Any narrowing of the trachea results in greatly increased resistance to air flow and local turbulence because the resistance to airflow is proportional to the reciprocal of the radius of the lumen to the fourth power. This increased resistance may further contribute to a cycle of increased respiratory efforts, cough, and inflammation. In addition, as described for canine chronic bronchitis, a continuing cycle of inflammation is also plausible as a result of mucosal damage. Mucus hypersecretion and airway obstruction impair normal mucociliary clearance, and inflammatory mediators amplify the response to irritants and organisms.

Clinically, tracheal collapse often occurs in conjunction with canine chronic bronchitis. In dogs with chronic bronchitis, the intrathoracic trachea is most often affected. Dogs with chronic bronchitis may initially demonstrate collapse of their major (mainstem and/or lobar) bronchi. The lumen of these airways is normally maintained by rafts of cartilage within their walls, rather than rings. Chronic exposure to inflammatory mediators presumably plays a role in the resultant loss of normal airway structure. In addition, obstruction of smaller airways because of excess mucus and mucosal alterations may decrease the intraluminal airway pressures in the larger airways during expiration and contribute to airway collapse. The general term for weakening of the normal tracheal and bronchial structure is *tracheobronchomalacia*.

As a result of intrathoracic and airway pressures, the extrathoracic trachea tends to collapse during inspiration. The intrathoracic trachea and mainstem and lobar bronchi tend to collapse during expiration.

#### **Clinical Features**

Tracheal collapse is common in middle-aged toy and miniature dogs, although it also can occur early in life and in large-breed dogs. Signs may occur acutely but then slowly progress over months to years. The primary clinical feature in most dogs is a nonproductive cough, described as a "goose honk." The cough is worse during excitement or exercise or when the collar exerts pressure on the neck. Eventually (usually after years of chronic cough), respiratory distress caused by obstruction to airflow may be brought on by excitement, exercise, or overheating. Systemic signs such as weight loss, anorexia, and depression are not expected. Occasionally, dogs are presented primarily for signs of upper airway obstruction without cough, also exacerbated during excitement, exercise, or hot weather. Stertorous sounds may be heard during periods of increased respiratory efforts. Such signs are usually the result of extrathoracic tracheal collapse. Tracheal collapse is rare in cats, and most often it occurs secondary to a tracheal obstruction such as a tumor or traumatic injury.

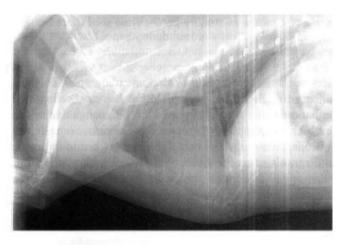

On physical examination a cough can usually be elicited by palpation of the trachea. An end-expiratory snap or click may be heard during auscultation if intrathoracic collapse is present. In advanced cases or after exercise, increased inspiratory effort may be observed in dogs with extrathoracic collapse and increased expiratory effort observed in those with intrathoracic collapse, often accompanied by audible sounds.

History and physical examination should also emphasize a search for exacerbating or complicating disease. The frequent association with canine chronic bronchitis has been mentioned. Other possibilities include cardiac disease causing left atrial enlargement with bronchial compression or pulmonary edema; airway inflammation caused by bacterial infection, allergic bronchitis, exposure to smoke (e.g., from cigarettes, fireplaces), or recent intubation; upper airway obstruction caused by elongated soft palate, stenotic nares, or laryngeal paralysis; and systemic disorders such as obesity or hyperadrenocorticism.

## Diagnosis

Collapsing trachea is most often diagnosed on the basis of clinical signs and the findings from cervical and thoracic radiography. Radiographs of the neck to evaluate the size of the lumen of the extrathoracic trachea are taken during inspiration (Fig. 21-6), when narrowing caused by tracheal collapse is more evident because of negative airway pressure. Conversely, the size of the lumen of the intrathoracic trachea is evaluated on thoracic radiographs taken during expiration, when increased intrathoracic pressures make collapse more apparent (Fig. 21-7). Radiographs of the thorax should also be taken during inspiration to detect concurrent bronchial or parenchymal abnormalities. (See Chapter 20 for further discussion of radiography.)

Fluoroscopic evaluation provides a "motion picture" view of large airway dynamics, making changes in luminal diam-

Lateral radiograph of the thorax and neck of a dog with collapsing trachea taken during inspiration. The extrathoracic airway stripe is severely narrowed cranial to the thoracic inlet.

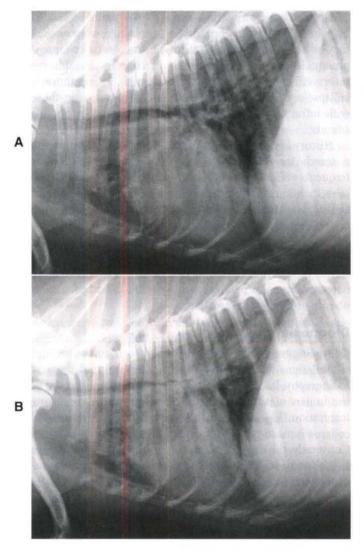

FIG 21-7
Lateral radiographs of a dog with tracheobronchomalacia.
During inspiration (A) the trachea and mainstem bronchi are nearly normal. During expiration (B) the intrathoracic trachea and mainstem bronchi are markedly narrowed.
Evaluation of the pulmonary parenchyma should not be attempted using films exposed during expiration.

eter easier to identify than by routine radiography. The sensitivity of fluoroscopy in detecting airway collapse is enhanced if the patient can be induced to cough during the evaluation by applying pressure to the trachea. Some degree of collapse is probably normal during cough, and in people a diagnosis of tracheobronchomalacia is generally made if the luminal diameter decreases by greater than 50% during forced exhalation.

Bronchoscopy is also useful in the diagnosis of airway collapse (Fig. 21-8; see also Fig. 21-3). The bronchi of smaller dogs may be difficult to evaluate by radiography or fluoroscopy but are easily examined bronchoscopically. Bronchoscopy and the collection of airway specimens (such as by BAL) is useful for identifying exacerbating or concurrent conditions.

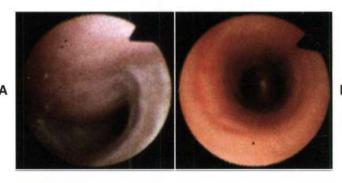

FIG 21-8
Bronchoscopic images from a dog with tracheal collapse
(A). The dorsal tracheal membrane is much wider than that of a normal dog (B). The airway lumen is greatly compromised.

Bronchoscopy is performed with the patient under general anesthesia, which interferes with the ability to induce cough. However, allowing the patient to reach a light plane of anesthesia combined with the manipulation of the airways will often cause more forceful respirations that increase the likelihood of identifying airway collapse.

Additional tests are performed to identify exacerbating or concurrent conditions. Tracheal wash fluid is analyzed by cytology and culture if bronchoscopy and BAL are not done. Other considerations include an upper airway examination, cardiac evaluation, and screening for systemic disease.

#### **Treatment**

Medical therapy is adequate treatment for most animals. In a study of 100 dogs by White et al. (1994), medical therapy resulted in resolution of signs for at least 1 year in 71% of cases. Dogs that are overweight are placed on a weight-reducing diet. Harnesses should be used instead of collars, and owners should be counseled to keep their dogs from becoming overheated (e.g., they should not be left in a car). Excessive excitement should also be avoided. Sedatives such as phenobarbital are prescribed for some animals, and these can be administered before known stressful events.

Cough suppressants are used to control signs and disrupt the potential cycle of perpetuating cough (see Table 21-1). The dose and frequency of administration of cough suppressants are adjusted as needed. Initially, high, frequent dosing may be needed to break the cycle of coughing. Subsequently, it is often possible to decrease frequency of administration and dose. Bronchodilators may be beneficial in dogs with signs of chronic bronchitis (see p. 290). Antiinflammatory doses of glucocorticoids can be given for a short period during exacerbation of signs (prednisone, 0.5 to 1 mg/kg q12h for 3 to 5 days, then tapered and discontinued over 3 to 4 weeks). Long-term use is not recommended because of potential detrimental side effects such as obesity, but this is often necessary to control signs in patients with chronic bronchitis. Dogs with signs referable to mitral insufficiency are managed for this disease (see Chapter 8). Dogs with abnormalities causing upper airway obstruction are treated with corrective surgical procedures.

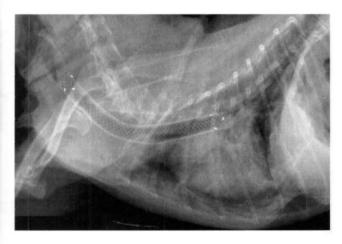

FIG 21-9
Lateral radiograph of the dog with tracheal collapse shown in Fig. 21-6 after placement of an intraluminal stent. The stent is has a meshlike structure and extends nearly the entire length of the trachea.

Antibiotics are not indicated for the routine management of a collapsing trachea. Dogs in which tracheal wash or BAL fluid analysis has revealed evidence of infection should be treated with appropriate antibiotics (selected on the basis of the results of sensitivity testing). Because most antibiotics do not reach high concentrations in the airways, relatively high doses of antibiotics should be administered for several weeks, as described for canine chronic bronchitis (p. 291). Any other potential related problems identified during the diagnostic evaluation are addressed.

Management of dogs in acute distress with signs of either extrathoracic airway obstruction or intrathoracic large airway obstruction is discussed in Chapter 26.

Surgical treatment of a collapsing trachea should be considered for animals that are no longer responsive to medical management, usually because of respiratory difficulty. The introduction of intraluminal stents has greatly reduced the morbidity and improved the success of surgical intervention. The most commonly used stents are self-expanding and made of nickel-titanium alloys (Fig. 21-9). In experienced hands, these stents are simple to place during a short period of anesthesia using fluoroscopic or bronchoscopic guidance. There is minimal morbidity associated with stent placement, and response is immediate and often dramatic. However, clinical signs (particularly cough) may not completely resolve, collapse of airways beyond the trachea and concurrent conditions are not directly addressed (often resulting in the continued need for medical management), and complications such as granuloma formation and stent fracture can occur. Results from stent placement are sufficiently encouraging that motivated clients with a dog that is failing medical management of tracheal collapse should be referred to someone experienced in stent placement for further consideration of this option.

#### **Prognosis**

In most dogs clinical signs can be controlled with conscientiously performed medical management, with diagnostic

evaluations performed during episodes of persistent exacerbations of signs. Animals in which severe signs develop despite appropriate medical care have a guarded prognosis, and motivated clients should be referred for possible stent placement.

#### **ALLERGIC BRONCHITIS**

Allergic bronchitis is a hypersensitivity response of the airways to an allergen or allergens. The offending allergens are presumably inhaled, although food allergens could also be involved. A definitive diagnosis requires identification of allergen(s) and resolution of signs after elimination of the allergen(s). Large controlled studies describing allergic bronchitis in dogs or cats are lacking. A study by Prost (2004) presented as an abstract found that 15 of 20 cats had positive intradermal skin tests to aeroallergens. For cats that reacted to storage mites or cockroach antigen, discontinuation of any dry food was recommended (i.e., only canned food was provided). Remission of signs occurred in 3 cats with only this treatment. Immunotherapy (desensitization) appeared to reduce or eliminate signs in some of the other cats. As a preliminary study, other treatments were also given to the study cats, and a control population was not described.

It is likely that some patients with allergic bronchitis are misdiagnosed because of difficulty in identifying specific allergens. In dogs long-standing allergic bronchitis may result in the permanent changes recognized as canine chronic bronchitis. In cats failure to identify specific allergen(s) results in a diagnosis of idiopathic feline bronchitis.

Allergic bronchitis in dogs may result in acute or chronic cough. Rarely, respiratory distress and wheezing occur. The physical examination and radiographic findings reflect the presence of bronchial disease, as described in the section on canine chronic bronchitis. Eosinophilic inflammation is expected in tracheal wash or BAL fluid. Heartworm tests and fecal examinations for pulmonary parasites are performed to eliminate parasitism as the cause of the eosinophilic inflammation. In dogs younger than than 2 years of age, bronchoscopic evaluation for *Oslerus osleri* also should be considered (see the following section). Allergic bronchitis in cats has the same presentation and results of diagnostic testing as described for idiopathic feline bronchitis, with eosinophilia expected in airway specimens.

Management of allergic bronchitis is initially focused on identifying and eliminating potential allergens from the environment (see the section on feline bronchitis). Diet trials with novel protein and carbohydrate sources also can be considered. According to the preliminary study previously described, a change in diet to canned food may be beneficial in some cases. Such experimentation with environment and diet is possible only in patients with clinical signs that are sufficiently mild to delay the administration of glucocorticoids and bronchodilators, as described in the sections on canine chronic bronchitis and feline bronchitis (idiopathic). Elimination trials can still be pursued once clinical signs are

controlled with medications, but confirmation of a beneficial effect will require discontinuation of the medication and, for a definitive diagnosis to be made, reintroduction of the allergen. The latter may not be necessary or practical in all cases.

#### **OSLERUS OSLERI**

#### **Etiology**

Oslerus osleri is an uncommon parasite of young dogs, usually those younger than 2 years of age. The adult worms live at the carina and mainstem bronchi and cause a local, nodular inflammatory reaction with fibrosis. First-stage larvae are coughed up and swallowed. The main cause of infection in dogs appears to be through intimate contact with their dam as puppies.

#### **Clinical Features**

Young affected dogs have an acute, loud, nonproductive cough and occasionally wheezing. The dogs appear otherwise healthy, making the initial presentation indistinguishable from that of canine infectious tracheobronchitis. However, the cough persists, and eventually airway obstruction occurs as a result of the formation of reactive nodules.

#### **Diagnosis**

Nodules at the carina occasionally can be recognized radiographically. Cytologic examination of tracheal wash fluid in some dogs shows the characteristic ova or larvae, providing the basis for a definitive diagnosis (see Table 20-1). Rarely, larvae are found in fecal specimens using zinc sulfate (s.g. 1.18) flotation (preferred) or the Baermann technique (see Box 20-8).

The most sensitive diagnostic method is bronchoscopy, which enables the nodules to be readily seen (Fig. 21-10). Brushings of the nodules are obtained and immediately evaluated cytologically to detect the larvae. Material can be examined directly in saline solution or stained with new methylene blue. If a definitive diagnosis is not obtained from analysis of the brushings, biopsy specimens are obtained.

#### **Treatment**

Treatment with ivermectin (400 µ g/kg orally or subcutaneously) is recommended. The same dose is administered again every 3 weeks for four treatments. This treatment has not been extensively investigated, however, and is not an approved use of this drug. It cannot be administered to Collies or related breeds. An alternative treatment is fenbendazole (50 mg/kg q24h for 7 to 14 days).

#### **Prognosis**

The prognosis for dogs treated with ivermectin is good; the drug appears to be successful in eliminating infection in the limited number of dogs that have been treated. Follow-up of individual patients is indicated to ensure successful elimination.

PULMONARY EDEMA

#### VIRAL PNEUMONIAS

#### **CANINE INFLUENZA**

#### Etiology

The canine influenza virus appears to be a recent adaptation from an equine influenza virus (Crawford et al., 2005). Serologic evidence has been found to support its existence among racing greyhounds since 1999 (Anderson et al., 2007). Therefore most dogs are susceptible to infection regardless of age, and spread among dogs in contact with one another, especially those housed together, is rapid. The virus is transmitted through respiratory secretions that are aerosolized or contaminate objects, including hands, clothing, bowls, and

kennels. Dogs are thought to shed the virus for up to 10 days after the first appearance of clinical signs, and shedding can also occur from the nearly 20% of infected dogs that never develop clinical signs (Crawford, 2005).

#### **Clinical Features**

The disease is most frequently identified during outbreaks among dogs in group housing, such as race tracks and animal shelters. Individual pets often have a recent history (usually in the previous week) of exposure to other dogs. Clinical signs of canine influenza in most dogs are similar to those of infectious tracheobronchitis (see p. 285). This mild form of the disease causes a cough that can be harsh and loud, as typically heard with infectious tracheobronchitis, but that is more often soft and moist. Some dogs may have concurrent mucopurulent nasal discharge, a less common finding in infectious tracheobronchitis.

Dogs with the severe form of disease develop overt pneumonia, peracutely or after having acough for up to 10 days (Crawford, 2005). Secondary bacteria infection is common. Presenting signs can include fever, increased respiratory rate progressing to respiratory distress, and auscultable crackles.

#### Diagnosis

A diagnosis of canine influenza should be considered in all dogs with acute cough until proven otherwise because it is highly transmissible to susceptible dogs. The diagnosis of pneumonia is made by the radiographic detection of a bronchointerstitial or bronchoalveolar pattern or both in dogs showing appropriate clinical signs. A tracheal wash is recommended to determine the types of bacteria involved and their antibiotic sensitivity.

Confirmation of the diagnosis of influenza is possible through several methods: serology, ELISA for antigen detection, virus isolation, and polymerase chain reaction (PCR) for viral RNA. Serology has several advantages compared with the other methods because blood is simple to collect, the resultant serum is stable, and infection can be detected even after viral shedding has ceased. However, rapid confirmation of the diagnosis is not possible through serology

because rising antibody titers are required to confirm the diagnosis. More timely results are possible with antigen detection (Directigen Flu A, Becton, Dickinson and Company) and PCR. Preliminary data by Spindel et al. (2007) using nasal swabs for specimens indicate that PCR is much more sensitive in detecting virus than antigen detection by ELISA or virus isolation. Other specimens that can be submitted for virus isolation or PCR are pharyngeal swabs, tracheal wash fluid, or lung tissue. Results from any test for viral detection can be falsely negative because of the relatively short period of shedding after the development of signs in many patients. For best results, samples are collected from febrile dogs very early in the course of disease.

#### **Treatment**

In dogs with the mild form of disease, cough will generally persist for several weeks even when treated with antibiotics and cough suppressants. Mucopurulent nasal discharge can be a result of secondary bacterial infection and may respond to antibiotics.

Dogs with pneumonia require aggressive supportive care, including intravenous fluid therapy if needed to maintain systemic (and therefore airway) hydration. A variety of bacteria have been isolated from infected dogs, including *Streptococcus equi* subsp. *zooepidemicus* and gram-negative organisms that are resistant to commonly prescribed antibiotics. Broad spectrum antibiotics should be prescribed initially and can be modified later on the basis of culture and sensitivity results and response to therapy. Initial choices include the combination of ampicillin with sulbactam and either a fluoroquinolone or an aminoglycoside or meropenem. (For additional information on treating bacterial pneumonia, see p. 304)

#### **Prognosis**

Most dogs that are exposed to the influenza virus will become infected. Dogs with the mild form of the disease fully recover, although cough may persist for as long as a month. The prognosis is more guarded for dogs that develop the severe form of the disease. Overall mortality has been reported to be <5% (Yoon et al., 2005).

#### **Prevention**

Vaccination is the most promising approach for prevention, but no vaccines are currently available. In veterinary hospitals, animal shelters, and other kenneling facilities, immediate isolation of dogs with signs of influenza is indicated and strict isolation protocols must be followed. The virus is readily killed by routine disinfectants. Successful prevention of spread of organisms depends on careful cleaning and disinfection of tables, cages, bowls, and any other objects in contact with infected dogs. In addition, strict attention to detail is necessary regarding hand cleaning after contact with any animal and using disposable barrier protection (e.g., gloves, booties, outerwear) when working with infected dogs or contaminated areas. Recommendations for managers and workers of kennel facilities are provided by the American

Veterinary Medical Association (www.avma.org/public\_health/influenza/canine\_guidelines.asp).

#### **OTHER VIRAL PNEUMONIAS**

Several other viruses can infect the lower respiratory tract, but rarely do signs of viral pneumonia predominate. The role of canine adenovirus 1 and parainfluenza virus in canine infectious tracheobronchitis has already been discussed (see Chapter 21). In dogs canine distemper virus can also infect the respiratory epithelium. Clinical signs of pneumonia usually result from a secondary bacterial pneumonia. Infection of the gastrointestinal tract or central nervous system can also occur in dogs with distemper (see Chapter 97). In cats, calicivirus can cause pneumonia, but this manifestation of infection is rare. The dry form of feline infectious peritonitis can affect the lungs, but cats are generally seen because of signs of involvement of other organs. Feline infectious peritonitis is discussed in Chapter 97.

#### **BACTERIAL PNEUMONIA**

#### **Etiology**

A wide variety of bacteria can infect the lungs. Common bacterial isolates from dogs and cats with pulmonary infections include Bordetella bronchiseptica, Streptococcus spp., Staphylococcus spp., Escherichia coli, Pasteurella spp., Klebsiella spp., Proteus spp., and Pseudomonas spp. Anaerobic organisms can be part of mixed infections, particularly in animals with aspiration pneumonia or with lung lobe consolidation. Mycoplasma organisms have been isolated from dogs and cats with pneumonia, but their exact role is not known.

Bacteria can colonize the airways, alveoli, or interstitium. The term *pneumonia* means inflammation of the lung, but the term is not specific for bacterial disease. Infection that clinically appears to be limited to the airways and peribronchial tissues is called *bacterial bronchitis*. If all three regions are involved, the disease is called either *bacterial bronchopneumonia* or *bacterial pneumonia*. Most cases of bacterial pneumonia result from bacteria of the oral cavity and pharynx entering the lungs via the airways, which causes a bronchopneumonia involving primarily the gravity-dependent cranial and ventral lung lobes (see Fig. 20-5). Bacteria that enter the lung through the hematogenous route usually cause pneumonia that assumes a caudal or diffuse pattern and marked interstitial involvement.

Bacterial pneumonia is a common lung disease, particularly in dogs. Community-acquired infectious pneumonia has been described in puppies (Radhakrishnan et al., 2007), most often caused by *Bordetella bronchiseptica* (49% of cases). However, consideration should also be given for predisposing abnormalities. *In adult dogs, a predisposing abnormality usually exists*. Abnormalities to consider in all patients include the aspiration of ingested material or gastric contents because of cleft palate, megaesophagus, or other causes of aspiration pneumonia (p. 309); decreased clearance from

the lungs of normally inhaled debris, particularly in animals with chronic bronchitis, ciliary dyskinesia, or bronchiectasis; immunosuppression resulting from drugs, malnutrition, stress, or endocrinopathies; other infections, including canine influenza, canine distemper, feline leukemia virus infection, or feline immunodeficiency virus infection; the inhalation or migration of foreign bodies; and, rarely, neoplasia or fungal or parasitic infections.

#### **Clinical Features**

Dogs and cats with bacterial pneumonia are evaluated because of respiratory signs, systemic signs, or both. Respiratory signs can include cough (which is usually productive and soft), a bilateral mucopurulent nasal discharge, exercise intolerance, and respiratory distress. Cough is less common in cats with pneumonia. Systemic signs include lethargy, anorexia, fever, and weight loss. The animal may have a history of chronic airway disease or regurgitation. Cats, particularly kittens, from stressful housing situations (e.g., overcrowding) appear predisposed to develop pneumonia as a result of Bordetella infections. Dogs with complicated infectious tracheobronchitis may have a recent history of harsh cough and a history consistent with exposure, as described in Chapter 21. Other potential predisposing factors, as listed in the preceding paragraph, are pursued through careful history taking.

Fever may be present on physical examination but is identified in only about half of patients. Crackles and occasionally expiratory wheezes may be auscultated, with the abnormal lung sounds often prominent over the cranioventral lung fields.

#### Diagnosis

Bacterial pneumonia is diagnosed on the basis of the complete blood count (CBC), thoracic radiograph findings, and the results from tracheal wash fluid cytologic analysis and bacterial culture. A CBC showing neutrophilic leukocytosis with a left shift, neutropenia with a degenerative left shift, or moderate-to-marked neutrophil toxicity is supportive of bacterial pneumonia. A normal or stress leukogram is as likely to be found.

Abnormal patterns on thoracic radiographs vary with the underlying disease. The typical abnormality is an alveolar pattern, possibly with consolidation, that is most severe in the dependent lung lobes (see Fig. 20-5). Increased bronchial and interstitial markings are also often present. Infections secondary to foreign bodies can be localized to any region of the lung. An interstitial pattern alone may be present in animals with early or mild disease or in those with infections of hematogenous origin. A bronchial pattern alone may be present in animals with a primarily bronchial infection. Radiographs are also evaluated for the presence of megaesophagus and other extrapulmonary disease.

Pulmonary specimens are evaluated cytologically and microbiologically (bacterial and ideally mycoplasmal cultures) to establish a definitive diagnosis and provide guidance in antibiotic selection. To maximize the diagnostic yield, specimens should be collected before antibiotic therapy is initiated. A tracheal wash specimen is generally sufficient. Septic neutrophilic inflammation is typically found in animals with bacterial pneumonia, and growth of organisms on bacterial culture is expected. Examination of a gramstained preparation will provide early guidance in antibiotic selection pending results of culture and will also assist in the identification of anaerobes or unusual organisms (e.g., *Mycobacteria* and filamentous organisms).

A conscientious effort is also made to identify any underlying problems. In some animals, such as those with megaesophagus, the initiating cause is obvious. Further diagnostic tests are indicated in other animals, depending on the results of the clinicopathologic evaluation. These may include bronchoscopy to search for airway abnormalities or foreign bodies, conjunctival scrapings to look for distemper virus, serologic tests to determine whether the animal has a fungal infection, tests for influenza virus, and hormonal assays to determine whether the animal has hyperadrenocorticism. Ciliary dyskinesia is discussed briefly in Chapter 21. The diagnostic evaluation for aspiration pneumonia is discussed on p. 309.

#### **Treatment**

#### **Antibiotics**

The treatment of bacterial pneumonia consists of antibiotics and supportive care, with follow-up evaluation (Box 22-1). The antibiotic sensitivity of the involved organisms is diffi-

BOX 22-1

Therapeutic Considerations for Bacterial Pneumonia

#### Antibiotics

Selected on basis of results from gram staining and culture and sensitivity testing of pulmonary specimens

#### **Airway Hydration**

Maintain systemic hydration Saline nebulization

#### Physiotherapy

Turning of recumbent animals every 1 to 2 hours Mild exercise of animals in stable condition Coupage

#### **Bronchodilators**

As needed, particularly in cats

#### Oxygen Supplementation

As needed

#### **AVOID**

Diuretics Cough suppressants Corticosteroids

cult to predict. Gram-negative infections and infections with multiple organisms are common. Antibiotics are initially selected on the basis of severity of clinical signs and the cytologic characteristics (i.e., morphology and gram-staining) of organisms found in pulmonary specimens. Antibiotic selection is subsequently modified, as needed, according to clinical response and sensitivity data from bacterial cultures of pulmonary specimens.

The extent to which an antibiotic can penetrate into the airway secretions does not need to be a major consideration in patients with bacterial pneumonia. Antibiotics generally achieve concentrations within the pulmonary parenchyma equal to those in plasma. Nebulization of antibiotics is rarely indicated.

For animals with mild or moderate clinical signs, antibiotics that can be initiated before sensitivity results are available include amoxicillin-clavulanate (20 to 25 mg/kg q8h), cephalexin (20 to 40 mg/kg q8h), or chloramphenicol (dogs, 50 mg/kg q8h; cats, 10 to 15 mg/kg q12h). Fluoroquinolones are reserved for animals with resistant gram-negative infections. Kittens from stressful environments suspected of having Bordetella-induced pneumonia should be treated with amoxicillin-clavulanate, doxycycline (5 to 10 mg/kg q12h; followed by a bolus of water), or fluoroquinolones while awaiting results of cultures. Doxycycline or a fluoroquinolone is more likely to be effective but has a greater potential for side effects in young kittens.

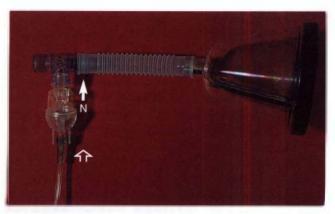

Animals with severe clinical signs or possible sepsis should be treated initially with intravenous antibiotics. Broad-spectrum coverage in animals with life-threatening infections can be achieved with meropenem (8 mg/kg q8h) or the combination of either ampicillin with sulbactam (22 mg/kg of ampicillin q8h) and a fluoroquinolone or ampicillin with sulbactam and an aminoglycoside (e.g., amikacin, 5 to 10 mg/kg q8h). Sulbactam is a beta-lactamase inhibitor, as is clavulanate, and the combination of ampicillin with sulbactam provides a drug with similar activity as amoxicillin-clavulanate in an intravenous formulation. If Toxoplasma infection is among the differential diagnoses, the combination of a fluoroquinolone and clindamycin or a fluoroquinolone and azithromycin can be used (see Chapter 99).

Antibiotic treatment should be continued for at least 1 week after the clinical signs resolve. Guidelines for patient monitoring are provided on p. 306.

#### **Airway Hydration**

The drying of secretions results in increased viscosity and decreased ciliary function, which interfere with the normal clearance mechanisms of the lung. Thus the water content of airway secretions must be maintained and airways must be hydrated in animals with pneumonia. Animals with any evidence of dehydration should receive fluid therapy. Diuretics can cause dehydration, and their use is contraindicated in such animals.

Additional moisture for the airways can be provided through humidification or nebulization. Such therapy is par-

Disposable jet nebulizers are readily available and inexpensive. Sterile saline solution is placed in the nebulizer (N). Oxygen enters the bottom of the nebulizer (open arrow), and nebulized air exits the top (closed arrow). Nebulized air is delivered to the animal with a face mask, as shown here, or it can be delivered into an enclosed cage.

ticularly recommended for animals with areas of consolidation or with suspected decreased airway clearance, such as those with bronchiectasis. Humidification refers to the saturation of air with water vapor. Depending on the temperature, the volume of water that remains as vapor is limited. The moisture reaches only the nasal cavity and the proximal trachea. Vaporization is not effective in hydrating deeper regions of the lungs. However, the more proximal effect can still provide some relief, particularly in animals with nasal discharge. Humidification is convenient and can be achieved simply by placing the animal in a steamy bathroom or in a small room with an inexpensive vaporizer, which is readily available at pharmacies.

Nebulization is necessary to provide moisture deeper into the airways. Nebulizers generate small, variably sized droplets, with a diameter ranging from 0.5 to 5 µm required to reach the deeper airways. Several types of nebulizers are available. Disposable jet nebulizers are readily available and inexpensive, and they can be attached to bottled oxygen or an air compressor (Fig. 22-1). Effective, inexpensive portable compressors are commercially available if needed for home use. The nebulized oxygen is delivered to the animal through a face mask. The particles can be seen as a mist.

Sterile saline solution is used as a nebulizing solution because it has mucolytic properties and is relatively nonirritating. Premedication with bronchodilators has been suggested as a way to reduce the bronchospasms, although use of saline alone in dogs does not usually cause problems. It is recommended that nebulization be performed two to six times daily for 10 to 30 minutes each time. Nebulization should be followed immediately by physiotherapy to promote the expectoration of exudate that may have increased in volume with rehydration. Nebulizers and tubing should be replaced after no more than 24 hours of use in actively infected patients, and face masks should be cleaned and disinfected.

#### **Physiotherapy**

Lying in one position impairs airway clearance, and lung consolidation can occur if one side remains dependent for prolonged periods. Therefore animals that are recumbent must be turned at least every 2 hours. Because activity causes animals to take deeper breaths and to cough, which promotes airway clearance, animals that are in a sufficiently stable condition and can tolerate the oxygen demands should be mildly exercised.

Physiotherapy is indicated after nebulization to promote coughing and facilitate the clearance of exudate from the lungs. Mild exercise is used when possible. Otherwise, coupage is performed. To perform coupage, the clinician strikes the animal's chest over the lung fields with cupped hands. The action should be forceful but not painful and should be continued for 5 to 10 minutes if tolerated by the patient. Coupage may also be beneficial for animals with lung consolidation that are not receiving nebulization.

#### **Bronchodilators**

Bronchospasm can occur secondary to inflammation, particularly in cats. Bronchodilators are used in animals showing increased respiratory efforts, particularly if expiratory wheezes are auscultated. Patient status should be monitored closely because bronchodilators may worsen ventilation:perfusion  $(\dot{V}/\dot{Q})$  mismatching, exacerbating hypoxemia. They are discontinued if clinical signs worsen or do not improve. Bronchodilators are discussed in Chapter 21 (cats, p. 290; dogs, p. 296).

#### Other Treatment

Expectorants are of questionable value in dogs and cats. Glucocorticoids are relatively contraindicated in animals with bacterial pneumonia. Oxygen therapy (see Chapter 27) is provided if the clinical signs, arterial blood gas measurements, or pulse oximetry measurements indicate a need for it.

#### Monitoring

Dogs and cats with bacterial pneumonia should be closely monitored for signs of deteriorating pulmonary function. Respiratory rate and effort and mucous membrane color are monitored at least twice daily. Thoracic radiographs and the CBC are evaluated every 24 to 72 hours. If the animal's condition does not improve within 72 hours, it may be necessary to alter treatment or perform additional tests. Animals showing improvement are sent home and reevaluated every 10 to 14 days. Once clinical and radiographic signs have resolved, antibiotic treatment is continued for an additional week.

The evidence of infection on initial radiographs can obscure that of focal disease processes such as neoplasia or foreign bodies, and focal opacities may not be apparent while an animal is receiving antibiotics. Therefore radiographs should be reevaluated approximately I week after antibiotic therapy has been discontinued in animals with recurrent infection or suspected localized disease. Persistence of local-

ized disease after long-term antibiotic therapy is an indication for bronchoscopy, thoracoscopy, or thoracotomy.

#### **Prognosis**

Bacterial pneumonia responds readily to appropriate therapy. The prognosis is more guarded in animals with underlying problems that predispose them to infection, and the likelihood of eliminating these problems must be taken into consideration.

Pulmonary abscess formation is an uncommon complication of bacterial pneumonia. Abscesses are seen as focal lesions on radiographs, and entire lobes may be involved. Horizontal-beam radiographs can be useful in determining whether the lesions are filled with fluid. Ultrasonography can also be helpful in characterizing areas of consolidation. Abscesses resolve in response to prolonged medical therapy in some animals, but if improvement is not observed or radiographic evidence of disease reappears after the discontinuation of therapy, surgical excision (i.e., lobectomy) is indicated.

#### **TOXOPLASMOSIS**

The lungs are a common site of involvement in cats with toxoplasmosis. Thoracic radiographs typically show fluffy alveolar and interstitial opacities throughout the lungs in such animals. Less often, a nodular interstitial, diffuse interstitial or bronchial pattern, lung lobe consolidation, or pleural effusion is seen. Organisms are rarely recovered from the lungs by tracheal wash. Bronchoalveolar lavage is more likely to retrieve organisms (see Fig. 20-17). Toxoplasmosis is a multisystemic disease and is discussed in detail in Chapter 99.

#### **FUNGAL PNEUMONIA**

The common mycotic diseases that can involve the lungs are blastomycosis, histoplasmosis, and coccidioidomycosis. In most cases, the organisms enter the body through the respiratory tract. The infection may be successfully eliminated without the animal showing clinical signs, or the animal may show only transient respiratory signs. The infection may also progress to cause disease involving the lungs alone or spread systemically to various target organs, or both processes may occur. Cryptococcal organisms also enter the body through the respiratory tract and can infect the lungs, particularly in cats. However, the presenting signs in cats are generally those of nasal infection. Pulmonary signs are most often the primary presenting complaint in dogs with blastomycosis and cats with histoplasmosis.

Pulmonary mycoses are considered in the differential diagnoses of dogs or cats with progressive signs of lower respiratory tract disease, especially if they occur in conjunction with weight loss, fever, lymphadenopathy, chorioretinitis, or other evidence of multisystemic involvement. Thoracic

radiographs typically show a diffuse, nodular, interstitial pattern of the lungs (see Fig. 20-6). The nodules are often miliary. The presence of this pattern in dogs with suspicious clinical signs supports a diagnosis of mycotic infection, but other diseases, including neoplasia, parasitic, or atypical bacterial (e.g., mycobacterial) infections and eosinophilic lung disease, can also produce similar patterns, so these must be borne in mind as well. Other potential radiographic abnormalities include alveolar and bronchointerstitial patterns and consolidated regions of lung. Hilar lymphadenopathy can occur, most commonly in animals with histoplasmosis. The lesions caused by histoplasmosis can also be calcified.

Organisms can occasionally be retrieved by tracheal wash. However, because of the interstitial nature of these diseases, bronchoalveolar lavage and lung aspiration are more likely to be successful (see Figs. 20-15 and 20-16). Fungal culture is probably more sensitive than cytologic analysis alone. An inability to find organisms in pulmonary specimens does not rule out the diagnosis of mycotic disease, however. A complete discussion of systemic mycoses is provided in Chapter 98.

#### **PULMONARY PARASITES**

Several parasites can cause lung disease. Certain intestinal parasites, especially *Toxocara canis*, can cause transient pneumonia in young animals, usually those younger than a few months of age, as the larvae migrate through the lungs. Infection with *Dirofilaria immitis* can result in severe pulmonary disease through inflammation and thrombosis (see Chapter 10). *Oslerus osleri* resides at the carina and mainstem bronchi of dogs and is discussed in Chapter 21. The other primary lung parasites that are most commonly diagnosed are *Capillaria* (*Eucoleus*) aerophila and *Paragonimus kellicotti* in dogs and cats, *Aelurostrongylus abstrusus* in cats, and *Crenosoma vulpis* in dogs.

Infection occurs as a result of the ingestion of infective forms, often within intermediate or paratenic hosts, that subsequently migrate to the lungs. An eosinophilic inflammatory response often occurs within the lungs, causing clinical signs in some, but not all, infected animals. The definitive diagnosis is made by the identification of the characteristic eggs or larvae in respiratory or fecal specimens (see Chapter 20).

#### CAPILLARIA (EUCOLEUS) AEROPHILA

Capillaria aerophila, also known as Eucoleus aerophila, is a small nematode. Adult worms are located primarily beneath the epithelial surfaces of the large airways. Clinical signs develop in very few animals with Capillaria infections, and the disease is most often identified through the fortuitous identification of characteristic eggs during routine fecal examinations.

The rare animal that displays signs has signs of allergic bronchitis. Thoracic radiograph findings are generally normal, although a bronchial or bronchointerstitial pattern may be seen. Tracheal wash fluid can show eosinophilic inflammation. *Capillaria* is diagnosed by the finding of characteristic eggs in tracheal wash fluid or fecal flotation material (see Fig. 20-12, *C*).

The treatment of choice for dogs and cats is fenbendazole (50 mg/kg orally q24h for 14 days). Levamisole (8 mg/kg orally for 10 to 20 days) has also been used successfully in dogs. Ivermectin has been suggested for treatment, but a consistently effective dosage has not been established. The prognosis in animals with the disease is excellent.

#### PARAGONIMUS KELLICOTTI

Paragonimus kellicotti is a small fluke. Snails and crayfish are both necessary intermediate hosts, thus limiting the disease to animals that have been in the region of the Great Lakes, in the Midwest, or in the southern United States. Pairs of adults are walled off by fibrous tissue, usually in the caudal lung lobes, with a connection to an airway to allow for the passage of eggs. A local granulomatous reaction may occur around the adults, or a generalized inflammatory response to the eggs may occur.

Infection is more common in cats than in dogs. Some dogs and cats have no clinical signs. When clinical signs are present, they may be the same as those seen in animals with allergic bronchitis. Alternatively, signs of spontaneous pneumothorax can result from the rupture of cysts.

The classic radiographic abnormality is single or multiple solid or cavitary mass lesions, most commonly present in the right caudal lobe (see Fig. 20-10). Other abnormal patterns seen on thoracic radiographs can be bronchial, interstitial (reticular or nodular), or alveolar in nature, depending on the severity of the inflammatory response (see Fig. 20-11).

Infection is diagnosed definitively through the identification of the ova in fecal specimens (using the sedimentation technique described in Chapter 20), tracheal wash fluid, or bronchoalveolar lavage fluid (see Fig. 20-12, *D*). Multiple fecal specimens should be examined in suspected cases because the eggs are not always present. A presumptive diagnosis is necessary in some cases. Note that ova from the tapeworm *Spirometra* spp. can be mistakenly identified as ova from *Paragonimus* (Fig. 22-2).

Fenbendazole is used to treat paragonimiasis at the same dosage as that recommended for the treatment of capillariasis. Alternatively, praziquantel can be used at a dosage of 23 mg/kg orally every 8 hours for 3 days.

Thoracocentesis should be used to stabilize the condition of animals with pneumothorax. If air continues to accumulate within the pleural space, however, it may be necessary to place a chest tube and perform suction until the leak has been sealed (see Chapter 24). Surgical intervention is rarely required.

The response to treatment is monitored by thoracic radiographs and periodic fecal examinations. Treatment may have to be repeated in some cases. The prognosis is excellent.

FIG 22-2
The operculated ova from Spirometra tapeworms (A) can be misdiagnosed as Paragonimus ova (B). The Spirometra ova are smaller and more pale than the yellow-brown Paragonimus ova. Most notably, Paragonimus ova have a distinctly visible shoulder (arrow) at the operculated end. (Courtesy James R. Flowers.)

#### **AELUROSTRONGYLUS ABSTRUSUS**

Aelurostrongylus abstrusus is a small worm that infects the small airways and pulmonary parenchyma of cats. Snails or slugs serve as intermediate hosts. Most cats with infection have no clinical signs. Those cats that do are usually young. The clinical signs are those of bronchitis. The abnormalities seen on radiographs may also reflect bronchitis, although a diffuse miliary or nodular interstitial pattern is present in some cats. Eosinophilic inflammation may be apparent in peripheral blood and airway specimens.

A definitive diagnosis is made through the identification of larvae, which may be present in fecal specimens prepared using the Baermann technique (see Fig. 20-12, A) or in airway specimens obtained by tracheal washing or bronchoalveolar lavage. Multiple fecal specimens should be examined in suspected cases because the larvae are not always present.

Cats should be treated with fenbendazole at the same dosage as that used for the treatment of capillariasis. In one study, the dosage of 50 mg/kg orally q24h for 15 days was effective in eliminating infection in all four cats treated (Grandi et al., 2005). In contrast with a previous report, ivermectin (0.4 mg/kg, administered subcutaneously) was not effective in one cat treated. The response to treatment is monitored by thoracic radiographs and periodic fecal examinations. Treatment may have to be repeated in some cases.

Antiinflammatory therapy with glucocorticoids alone often causes the clinical signs to resolve. However, eliminating the underlying parasitic disease is a preferable treatment

goal, and glucocorticoid therapy may interfere with the effectiveness of the antiparasitic drugs. Bronchodilators may provide symptomatic relief and presumably do so without interference with antiparasitic drug action. The prognosis in animals with the infection is excellent.

#### CRENOSOMA VULPIS

Crenosoma vulpis is a lungworm of foxes that can also infect dogs. Dogs living in Atlantic Canada and parts of Europe are most commonly diagnosed with this disease, while the diagnosis remains rare in the United States. However, it is possible that with increased residential development into fox habitats, the frequency of cases in this country will increase. The worm resides in the airways (i.e., trachea, bronchi, bronchioles). Snails or slugs serve as intermediate hosts. The clinical signs are those of allergic or chronic bronchitis. Thoracic radiographs may have a bronchointerstitial or patchy alveolar pattern or occasionally a nodular pattern. Infection is diagnosed definitively through the identification of the larvae in fecal specimens using the Baermann technique described in Box 20-8, tracheal wash fluid, or bronchoalveolar lavage fluid (see Fig. 20-12, B). Multiple fecal specimens should be examined in suspected cases because the larvae are not always present. A single oral dose of milbemycin oxime (0.5 mg/kg) was effective in resolving clinical signs and elimination of larvae from feces collected 4 to 6 weeks after treatment in 32 dogs (Conboy, 2004). This treatment may not be effective against immature larvae. As with other pulmonary parasites, the response to treatment is monitored with thoracic radiographs and periodic fecal examinations.

#### **ASPIRATION PNEUMONIA**

#### Etiology

A small amount of fluid and bacteria is aspirated from the oropharynx into the airways of healthy animals, but normal airway clearance mechanisms prevent infection. Organisms from the oropharynx are thought to be the source of bacteria in many animals with bacterial pneumonia, specifically bacterial bronchopneumonia (see p. 303). In people such infection is termed aspiration pneumonia. In veterinary medicine the term aspiration pneumonia is generally used to refer to the inflammatory lung disease that occurs as a result of the inhalation of overt amounts of solid or liquid material into the lungs. The materials that are usually aspirated are stomach contents or food. Normal laryngeal and pharyngeal function prevents aspiration in healthy animals, although occasionally an excited puppy or a dog running through tall grass aspirates a foreign body. Otherwise, the presence of aspiration pneumonia in an animal of any age indicates an underlying predisposing abnormality (Box 22-2).

Aspiration pneumonia is a common complication of animals with regurgitation. Megaesophagus is the most common cause of regurgitation (see Chapter 31). Other causes of regurgitation (e.g., reflux esophagitis, esophageal obstruction) are less common. Another cause of aspiration pneumonia is localized or systemic neurologic or muscular disease affecting the normal swallowing reflexes of the larynx or pharynx. These reflexes can also be depressed in dogs or cats with abnormal levels of consciousness or in those that are anesthetized. Laryngeal paralysis does not always lead to the development of aspiration pneumonia, but aspiration is a potential complication of therapeutic laryngoplasty. It can also occur in animals with abnormal pharyngeal anatomy resulting from mass lesions, brachycephalic airway syndrome, or cleft palate. Bronchoesophageal fistulae are a rare cause of aspiration pneumonia.

Aggressive force-feeding, especially in mentally depressed animals, and improper placement of stomach tubes into the trachea are iatrogenic causes of aspiration pneumonia. Mineral oil administered to prevent hairballs can be a cause of aspiration pneumonia in cats because the tasteless and odorless oil is poorly handled by the pharynx.

The damage to the lung resulting from aspiration may stem from chemical damage, obstruction of the airways, infection, and the resulting inflammatory response to each of these factors. Gastric acid causes severe chemical injury to the lower airways. Tissue necrosis, hemorrhage, edema, and bronchoconstriction ensue, and a marked acute inflammatory response is initiated. Hypoxemia resulting from decreased alveolar ventilation and compliance can be fatal.

Severe respiratory distress can occur from physical obstruction of the airways by the aspirated material. In most cases only small airways are obstructed, but rarely a large piece of food will obstruct a major airway. Obstruction is subsequently exacerbated by reflex bronchoconstriction and inflammation. Inhaled solid material initiates an inflammatory reaction that includes an abundance of macrophages.

- \* Discussions of these abnormalities can be found on the given chapter numbers.
- \*\*Overzealous feeding, incorrect tube placement, or loss of lower esophageal sphincter competence because of presence of tube.

This response can become organized, resulting in the formation of granulomas.

Bacterial infection may result from the aspiration of contaminated material, such as ingesta that remained in the esophagus. Acidic gastric contents are probably sterile, although in people the contents are considered contaminated if antacids have been taken, if an intestinal obstruction is present, or with periodontal disease. Note that many veterinary patients have periodontal disease. Regardless of the sterility of the aspirated material, the resultant damage to the lungs by gastric acid greatly predisposes the animal to the development of a secondary infection.

The inhalation of mineral oil elicits a chronic inflammatory response. The clinical signs in this setting are often mild, but in rare instances they may be severe. Radiographic abnormalities persist and can be erroneously interpreted as representing neoplastic lesions.

#### **Clinical Features**

Dogs and cats with aspiration pneumonia are frequently presented for acute, severe respiratory signs. Systemic signs such as anorexia and depression are common, and these patients may even present in shock. Vomiting, regurgitation, or eating may have preceded the onset of distress. Other patients are seen because of chronic intermittent or progressive signs of coughing or increased respiratory efforts. Occasionally, patients show only signs of depression or the predisposing disease. A thorough history is obtained, with all organ systems carefully reviewed. The owners are specifically questioned about force-feeding and medication administration.

Fever may be present, but it is an inconsistent finding. Crackles are often auscultated, particularly over the dependent lung lobes. Wheezes are heard in some cases. Once a patient is in stable condition, a thorough neuromuscular examination is performed. The ability of the patient to prehend and swallow food and water should also be observed.

#### **Diagnosis**

Aspiration pneumonia is usually diagnosed on the basis of the suggestive radiographic findings in conjunction with evidence of a predisposing condition. Thoracic radiographs typically show diffuse, increased interstitial opacities with alveolar flooding (air bronchograms) and consolidation of the dependent lung lobes (see Fig. 20-5). Radiographic abnormalities may not be apparent until 12 to 24 hours after aspiration, however. Occasionally, nodular interstitial patterns are seen in chronic cases. Large nodules can form around solids; miliary nodules often form in animals that have aspirated mineral oil. Large airway obstruction is suspected if radiographs show a soft-tissue mass within a large airway, but this is an unusual finding. A marked, diffuse alveolar pattern can be seen in dogs that have severe secondary edema (see the section on pulmonary edema, p. 319).

The peripheral blood count can reflect the pulmonary inflammatory process, but it is often normal. Neutrophils are examined for the presence of toxic changes suggestive of sepsis.

Tracheal wash is indicated for all animals that can tolerate the procedure to identify complicating bacterial infection and obtain antibiotic sensitivity data. A marked inflammatory response characterized by a predominance of neutrophils is seen in cytologic specimens. Blood resulting from hemorrhage may be seen in specimens from animals in the acute period after aspiration. Bacteria may also be seen. Bacterial cultures should always be performed.

Bronchoscopy can be used to grossly examine the airways and detect and remove large solids. However, the likelihood of a large airway obstruction is very small, so bronchoscopy is performed only if there are clear signs of large airway obstruction (see Chapter 26) or if the animal is not conscious and therefore does not require general anesthesia for the procedure.

Blood gas analysis can be helpful in differentiating hypoventilation from ventilation-perfusion abnormalities (see Chapter 20), although a combination of abnormalities exists in most animals with aspiration pneumonia. Animals with evidence of profound hypoventilation may have either a large airway obstruction or muscle weakness secondary to an underlying neuromuscular disorder such as myasthenia gravis. Blood gas analysis also assists in the therapeutic management of these animals and can be used effectively to monitor the response to therapy.

Diagnostic evaluation is indicated to identify potential underlying diseases (see Box 22-2). This may include a thorough oral and pharyngeal examination, contrast-enhanced radiographic studies to evaluate the esophagus, or specific neuromuscular tests.

#### **Treatment**

Suctioning of the airways is helpful only for animals that aspirate in the hospital while already anesthetized or unconscious, when it can be performed immediately after aspiration. If a bronchoscope is immediately available, suctioning can be performed through the biopsy channel, which affords visualized guidance. Alternatively, a sterile soft rubber tube attached to a suction pump can be passed blindly into the airways through an endotracheal tube. Excessive suction may result in lung lobe collapse. Therefore low-pressure, intermittent suction is used, followed by expansion of the lungs with several positive-pressure ventilations using an anesthetic or Ambu bag. Airway lavage is contraindicated.

Animals in severe respiratory distress should be treated with fluid therapy, oxygen supplementation, bronchodilators, and glucocorticoids. Fluids are administered intravenously at high rates to treat shock (see Chapter 30) and should be continued after initial stabilization of the animal's condition to maintain systemic hydration, which is necessary to maximize the effectiveness of airway clearance mechanisms. However, overhydration must be avoided because of a tendency for pulmonary edema.

Oxygen supplementation (see Chapter 27) is initiated immediately in compromised animals. Positive-pressure ventilation is required for animals in severe respiratory distress that is unresponsive to oxygen therapy.

Bronchodilators can be administered to decrease bronchospasms and ventilatory muscle fatigue. They are most likely to be effective in cats. Bronchodilators can worsen ventilation:perfusion  $(\dot{V}/\dot{Q})$  mismatching, exacerbating hypoxemia. They are discontinued if no improvement is seen or clinical signs appear to worsen after their administration.

Rapid-acting glucocorticoids are administered for the treatment of shock. Their use in the absence of shock is controversial. The antiinflammatory effects of glucocorticoids can be beneficial, but glucocorticoids can interfere with normal host defense mechanisms in tissues that have already been severely compromised. This author reserves the use of glucocorticoids for patients that have severe respiratory

compromise and a deteriorating clinical picture despite appropriate antibiotic therapy and supportive care. Low (antiinflammatory) doses of short-acting preparations are administered for up to 48 hours.

Animals with a large airway obstruction can benefit from bronchoscopy and foreign body removal. However, routine bronchoscopy is not indicated because of the risk of the general anesthesia needed during the procedure and the infrequency of large airway obstructions.

Antibiotics are administered immediately in animals that are presented in severe distress or with overt systemic signs of sepsis. Selected antibiotics should have a broad spectrum of activity and be administered intravenously. Such drugs include meropenem or combinations of either ampicillin with sulbactam and a fluoroquinolone or ampicillin with sulbactam and an aminoglycoside (see the section on bacterial pneumonia, p. 303).

A tracheal wash is performed in stable patients before initiation of antibiotics to document the presence of infection and obtain antibiotic sensitivity data. This information is particularly valuable because prolonged treatment is often needed and also because research in human medicine has amply demonstrated that resistant secondary infections can develop after aspiration in patients given antibiotics initially or on an empirical basis. As discussed for bacterial pheumonia, the high incidence of gram-negative and mixed infections make assumptions regarding antibiotic sensitivity prone to error. Pending results of culture, it is reasonable to initiate treatment with a penicillin with a beta-lactamase inhibitor (e.g., amoxicillin-clavulanate or ampicillin with sulbactam). Because infection can occur as allater complication in these patients, frequent monitoring with physical examination, CBC, and thoracic radiographs is necessary to detect any deterioration consistent with secondary infection. Tracheal wash is repeated if infection is suspected.

Further therapeutic and monitoring considerations are discussed in the section on bacterial pneumonia (p. 303). Underlying diseases are treated to prevent recurrence.

#### **Prognosis**

Animals with mild signs of disease and a correctable underlying problem have an excellent prognosis. The prognosis is worse for animals with more severe disease or uncorrectable underlying problems.

#### EOSINOPHILIC LUNG DISEASE (PULMONARY INFILTRATES WITH EOSINOPHILS AND EOSINOPHILIC PULMONARY GRANULOMATOSIS)

Eosinophilic lung disease is a broad term describing inflammatory lung disease in which the predominant infiltrating cell is the eosinophil. Eosinophilic inflammation can involve primarily the airways or the interstitium. Allergic bronchitis and idiopathic bronchitis are by far the most common eosinophilic lung diseases seen in cats and are discussed in Chapter 21. Interstitial infiltration, with or without concurrent bronchitis, is sometimes referred to as *pulmonary infiltrates with eosinophils (PIE)* and is typically seen in dogs. *Eosinophilic pulmonary granulomatosis* is a severe type of PIE seen in dogs and is characterized by the development of nodules and often hilar lymphadenopathy. It must be differentiated from a mycotic infection and neoplasia. The term *eosinophilic bronchopneumopathy* is also used to describe eosinophilic lung disease. These names are descriptive only and likely encompass a variety of hypersensitivity disorders of the lung.

Because eosinophilic inflammation is a hypersensitivity response, an underlying antigen source is actively pursued in affected animals. Considerations include heartworms, pulmonary parasites, drugs, and inhaled allergens. Food allergy could play a role in these disorders, but this association has not been explored. Potential allergens are discussed further in the section on allergic bronchitis, Chapter 21. Bacteria, fungi, and neoplasia can also induce a hypersensitivity response, but this response often is not the predominant finding. In many cases no underlying disease can be found. Eosinophilic pulmonary granulomatosis is strongly associated with heartworm disease.

#### Clinical Features

Eosinophilic lung diseases are seen in young and older dogs. Affected dogs are evaluated because of progressive respiratory signs, such as cough, increased respiratory efforts, and exercise intolerance. Systemic signs such as anorexia and weight loss are usually mild. Lung sounds are often normal, although crackles or expiratory wheezes are possible.

#### **Diagnosis**

The finding of peripheral eosinophilia is included in some definitions of PIE, but it is not present in all animals with the disease, nor is it a specific finding. A diffuse interstitial pattern is seen on thoracic radiographs. Eosinophilic pulmonary granulomatosis results in the formation of nodules, usually with indistinct borders. These nodules can be quite large, and hilar lymphadenopathy may also be present. A patchy alveolar opacity and consolidation of the lung lobes can occur as well.

Pulmonary specimens must be examined to establish a diagnosis of PIE. In some cases of PIE, evidence of eosino-philic inflammation may be found in tracheal wash fluid. More aggressive techniques for collecting pulmonary specimens, such as bronchoalveolar lavage, lung aspiration, or lung biopsy, are required to identify the eosinophilic response in other cases. Other inflammatory cell populations are frequently present in lesser numbers in such specimens.

Potential antigen sources should be considered, and pulmonary specimens should be carefully examined for the presence of infectious agents and features of malignancy. Heartworm tests and fecal examinations for pulmonary parasites are indicated in all cases.

#### **Treatment**

Any primary disease identified during the diagnostic evaluation of these animals is treated directly. Eliminating the source of the antigen that may be triggering the excessive immune response may result in a cure.

Antiinflammatory therapy with glucocorticoids is indicated for dogs in which an antigen source cannot be identified and for dogs with heartworm disease if the cosin-ophilic inflammation is causing respiratory compromise (see Chapter 10). Dogs with eosinophilic granulomatosis often require more aggressive immunosuppressive therapy.

Dogs are typically treated with glucocorticoids, such as prednisone, at an initial dosage of 1 to 2 mg/kg orally every 12 hours. Clinical signs and thoracic radiographs are used to monitor the animal's response to therapy, and initially these should be assessed every week. Once the clinical signs have resolved, the dosage of glucocorticoids is decreased to the lowest effective one. If signs have remained in remission for 3 months, discontinuation of therapy can be attempted. If signs are exacerbated by glucocorticoid therapy, immediate reevaluation to search for underlying infectious agents is indicated.

Dogs with large nodular lesions (eosinophilic granulomatosis) should be treated with a combination of glucocorticoids and a cytotoxic agent. Prednisone is administered to these animals at a dosage of 1 mg/kg orally every 12 hours, in combination with cyclophosphamide at a dosage of 50 mg/m<sup>2</sup> orally every 48 hours. Clinical signs and thoracic radiographs are evaluated every 1 to 2 weeks until remission is achieved. CBCs are also done every 1 to 2 weeks to detect excessive bone marrow suppression resulting from the cyclophosphamide. Attempts to discontinue therapy can be made after several months of remission. It may be necessary to discontinue the cyclophosphamide earlier than this because long-term treatment is associated with sterile hemorrhagic cystitis. (See Chapter 78 for further discussion of the adverse effects of cyclophosphamide therapy.) The effectiveness of other immunosuppressive drugs, such as cyclosporine, have not been reported,

#### **Prognosis**

A wide spectrum of disease is seen in terms of both the severity of the signs and the underlying causes. The prognosis is generally fair to good. However, the prognosis is guarded in dogs with severe eosinophilic pulmonary granulomatosis.

#### IDIOPATHIC INTERSTITIAL PNEUMONIAS

The term *idiopathic interstitial pneumonia* generally denotes inflammatory and/or fibrotic infiltration of the lungs involving primarily the alveolar septa. Small airways, alveoli, and the pulmonary vasculature may also be affected. The alveolar

septa include alveolar epithelium, epithelial basal lamina, capillary endothelial basal lamina, and capillary endothelium. Other cells include fibroblasts and alveolar macrophages. To make a diagnosis of idiopathic disease, the known etiologies of interstitial lung disease must be ruled out as completely as possible. Etiologies of interstitial lung disease are numerous and include many infectious agents and some toxins and neoplasia.

Idiopathic pulmonary fibrosis is the most well-described idiopathic interstitial pneumonia in dogs and cats. Some of the eosinophilic lung diseases (not including allergic or idiopathic feline bronchitis) may also be part of this group of diseases (see p. 311). Other inflammatory lung diseases of the interstitium in which a cause cannot be identified are occasionally seen in dogs and cats. The lesions may represent a form of vasculitis, a component of systemic lupus erythematosus, immune complex disease, or some other hypersensitivity response. These diseases are rare, however, and not well documented. A lung biopsy must be performed for a definitive diagnosis to be made. A clinical diagnosis is made only after extensive testing has been done to rule out more common causes of lung disease, particularly infectious agents and neoplasia, and after a prolonged positive response to immunosuppressive therapy. Lymphomatoid granulomatosis is a nodular interstitial disease that exhibits clinical signs similar to those seen in animals with eosinophilic pulmonary granulomatosis. It was initially considered to be an inflammatory lung disease but is currently considered to be lymphoproliferative neoplasia of the lung (see p. 314).

#### **IDIOPATHIC PULMONARY FIBROSIS**

In people idiopathic pulmonary fibrosis is the clinical diagnosis that is defined by the histopathologic diagnosis of usual interstitial pneumonia. However, the histopathologic pattern of usual interstitial pneumonia can be seen as a result of other diseases, and according to the American Thoracic Society/European Respiratory Society consensus statement (2002), the diagnosis of idiopathic pulmonary fibrosis also requires (1) the exclusion of other known causes of interstitial lung diseases including drug toxicities, environmental exposures, and collagen vascular diseases; (2) characteristic radiographic or computed tomographic abnormalities; and (3) characteristic pulmonary function abnormalities. In veterinary medicine the latter criterion may be difficult to apply, but attention should be paid to the other criteria.

The characteristic lesions that result in the histopathologic pattern of usual interstitial pneumonia are as follows: fibrosis, areas of fibroblast proliferation, metaplasia of the alveolar epithelium, and mild to moderate inflammation. Honeycomb change may occur as a result of enlarged airspaces lined by abnormal alveolar epithelium. The lungs are heterogeneously affected, with areas of normal lung intermixed with abnormal regions. The abnormal regions are often subpleural. A defect in wound healing has been hypothesized as the cause.

Idiopathic pulmonary fibrosis has been recently described in cats on the basis of histologic lesions which are quite

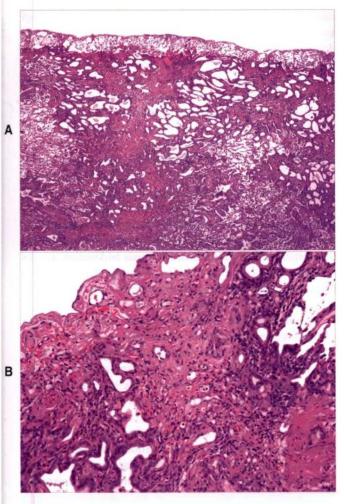

FIG 22-3

Photomicrographs of a lung biopsy from a cat with idiopathic pulmonary fibrosis. At lower power (A) there is distortion and obliteration of the normal pulmonary architecture because of replacement of the parenchyma with disorganized bands of fibrous tissue and scattered mononuclear inflammatory cells. There are few recognizable alveoli in this section. The alveolar septae are thickened, and metaplasia of the alveolar epithelium is present. At higher power (B) subpleural alveoli show marked distortion with marked septal fibrosis and type 2 epithelial hyperplasia. Although normal areas of the lung are not shown, the disease is characterized by heterogeneity of lesions within the lung. (Photomicrographs courtesy Stuart Hunter.)

similar to those in people (Cohn et al., 2004; Williams et al., 2006; Fig. 22-3). Unlike the disease that affects people and cats, the disease in dogs has been associated with the primary lesion of collagen deposition in the alveolar septa with no fibroblastic foci (Norris et al., 2005).

Neoplasia can occur concurrently with idiopathic pulmonary fibrosis in people and was reported in 6 of 23 cats (Cohn et al., 2004). The lesions of pulmonary fibrosis can also be misinterpreted as carcinoma, and 4 of 23 cats considered to have pulmonary fibrosis were initially given a pathologic diagnosis of carcinoma.

#### **Clinical Features**

A breed predisposition is seen in dogs with pulmonary fibrosis. West Highland White Terriers are most frequently reported, with fewer cases documented among Staffordshire Bull Terriers, Jack Russell Terriers, Cairn Terriers, and Schipperkes. Both dogs and cats tend to be middle-aged or older at the time of presentation, although characteristic signs have been found in patients as young as 2 years of age.

Signs are most often slowly progressive over months. In cats the duration of signs may be shorter, with 6 of 23 cats having shown signs for only 2 days to 2 weeks (Cohn et al., 2004). Respiratory compromise is the most prominent clinical sign of pulmonary fibrosis, manifested as exercise intolerance and/or rapid, labored breathing. Cough often occurs, but if it is the predominant sign, higher consideration for a diagnosis of bronchitis should be given. Syncope may occur in dogs.

Crackles are the hallmark auscultatory finding in dogs and are noted in some cats. Wheezes are heard in approximately half of dogs and some cats. The abnormal breathing pattern is typically tachypnea with relatively effortless expiration.

#### **Diagnosis**

Thoracic radiographs of dogs with pulmonary fibrosis typically show a diffuse interstitial pattern. The abnormal densities generally must be moderate to severe to be distinguished from age-related change. A bronchial pattern is often noted concurrently, contributing to the overlap in signs between pulmonary fibrosis and chronic bronchitis. Evidence of pulmonary hypertension may be seen (see p. 316). Radiographs of cats with this disease may show diffuse or patchy infiltrate (Fig. 22-4). Patterns may be interstitial, bronchial, alveolar, or mixed but are often quite severe. Bronchiectasis, caused by traction on the airways, may be noted in either species with advanced disease.

Results of the CBC, serum biochemistry panel, and urinalysis are generally unremarkable. Polycythemia may be present secondary to chronic hypoxemia. Screening tests to identify other etiologies of interstitial lung disease include fecal examinations for parasites, heartworm tests, and appropriate infectious disease serology.

Airway specimens should be collected in sufficiently stable patients, primarily to assist in the identification of other causes of lung disease. Mild to moderate inflammation may be seen in patients with pulmonary fibrosis, but this is a nonspecific finding. Bronchoscopy may also be useful in some patients for identifying other causes of lung disease, such as chronic bronchitis.

Typical lesions identified by computed tomography are often used in making a presumptive diagnosis of idiopathic pulmonary fibrosis in people. Similar lesions may be seen in some dogs with the disease (Johnson et al., 2005). Results of computed tomography in cats have not been reported.

A definitive diagnosis of pulmonary fibrosis requires a lung biopsy obtained by thoracotomy or thoracoscopy. The expense and invasiveness of biopsy preclude its use in some

#### FIG 22-4

Lateral thoracic radiograph from a cat with idiopathic pulmonary fibrosis showing a diffuse interstitial pattern with patchy areas of alveolar disease in the caudal lung lobes. Pericardial and mediastinal fat are also seen. Radiographic abnormalities in cats with fibrosis are quite variable, including the range of interstitial, bronchial, alveolar, or mixed patterns.

patients. Furthermore, the lack of specific treatment recommendations for pulmonary fibrosis is a deterrent. However, biopsy should be considered in patients that are stable and whose owners have sufficient resources. The less invasive tests cannot completely rule out the existence of a different, directly treatable disease (e.g., atypical bacterial infection, fungal disease, parasitism), and more aggressive treatment for pulmonary fibrosis could be recommended with histologic confirmation of the diagnosis.

#### **Treatment**

Even in people, large, well-controlled studies have not been performed to determine the ideal treatment strategy for idiopathic pulmonary fibrosis (Hoyles et al., 2006). Most individuals are treated with prednisone at low dosages and azathioprine. Cyclophosphamide is used routinely by some physicians and only during exacerbations by others. Corticosteroids alone are not considered to be effective. Many other drugs, including colchicine and penicillamine, have been tried or investigated, but thus far none have been proved convincingly effective. Survival rates 5 years after the diagnosis remain only 20% to 30% with treatment.

Most dogs and cats have been treated with corticosteroids and bronchodilators. Theophylline derivatives have the theoretical potential to provide some benefit through potentiation of steroid activity. On the basis of clinical experience with people, the addition of azathioprine or cyclophosphamide may be of benefit. Animals with severe pulmonary hypertension may benefit from treatment of this complication (p. 316).

#### **Prognosis**

The prognosis for idiopathic pulmonary fibrosis in dogs and cats is poor, with relentless progression of disease expected.

Nevertheless, individual patients, particularly dogs, can survive for longer than a year. The mean survival time in dogs in one study was 18 months from the onset of signs, with survival up to 3 years (Corcoran et al., 1999). The prognosis in cats is poorer. Of 23 cats, 14 died or were euthanized within weeks of the onset of signs and only 7 of 23 survived longer than 1 year (Cohn et al., 2004).

#### **PULMONARY NEOPLASIA**

Primary pulmonary tumors, metastatic neoplasia, and multicentric neoplasia can all involve the lungs. Most primary pulmonary tumors are malignant. Carcinomas predominate and include adenocarcinoma, bronchoalveolar carcinoma, and squamous cell carcinoma. Sarcomas and benign tumors are much less common. Small cell carcinoma, or oat cell tumor, which occurs frequently in people, is rare in dogs and cats.

The lungs are a common site for the metastasis of malignant neoplasia from other sites in the body and even from primary pulmonary tumors. Neoplastic cells can be carried in the bloodstream and trapped in the lungs, where there is low blood flow and an extensive capillary network. Lymphatic spread or local invasion can also occur.

Multicentric tumors can involve the lungs. Such tumors include lymphoma, malignant histiocytosis, and mastocytoma. An unusual lymphoproliferative tumor limited to involvement of the lung is *lymphomatoid granulomatosis*. This neoplasm is characterized by the infiltration of pleomorphic lymphoreticular and plasmacytoid cells around and into blood vessels, with accompanying eosinophils, neutrophils, lymphocytes, and plasma cells.

Multiple tumors of different origins can occur in the same animal. In other words, the presence of a neoplasm in one site of the body does not necessarily imply that the same tumor is also present in the lungs.

#### **Clinical Features**

Neoplasms are most common in older animals but also occur in young adult animals. Tumors involving the lungs can produce a wide spectrum of clinical signs. These signs are usually chronic and slowly progressive, but peracute manifestations such as pneumothorax or hemorrhage can also occur.

Most signs reflect respiratory tract involvement. Infiltration of the lung by the tumor can cause interference with oxygenation, leading to increased respiratory efforts and exercise intolerance. Mass lesions can compress airways, provoking cough and obstructing ventilation. Erosion through vessels can result in pulmonary hemorrhage. The blood loss can be sudden, resulting in acute hypovolemia and anemia in addition to respiratory compromise. Edema, nonseptic inflammation, or bacterial infection can occur secondary to the tumor. Erosion through the airways can result in pneumothorax. Pleural effusion of nearly any character can form.

In rare cases, the caudal or cranial venae cavae are obstructed, resulting in the development of ascites or head and neck edema, respectively.

Nonspecific signs in dogs and cats with pulmonary neoplasms include weight loss, anorexia, depression, and fever. Gastrointestinal signs may be the primary complaint. Vomiting and regurgitation may be the presenting signs in cats in particular. Lameness may be the presenting sign in patients with hypertrophic osteopathy secondary to thoracic mass lesions and in cats with metastasis of carcinoma to their digits.

Some animals with lung neoplasia have no clinical signs at all, and the tumor is discovered as an incidental finding on thoracic radiographs or at postmortem examination. Animals with metastatic or multicentric lung neoplasia can be seen because of signs of tumor involvement in another organ.

Lung sounds may be normal, decreased, or increased. They are decreased over all lung fields in animals with pneumothorax or pleural effusion. Localized decreased or increased lung sounds can be heard over regions that are consolidated. In a few patients, crackles and wheezes can be auscultated. There may be evidence of other organ involvement or hypertrophic osteopathy.

#### **Diagnosis**

Neoplasia is definitively diagnosed through the histologic or cytologic identification of criteria of malignancy in populations of cells in pulmonary specimens (Fig. 22-5). Thoracic radiographs are commonly evaluated initially, and findings can support a tentative diagnosis of neoplasia. Radiographs can also be used to identify the location of disease, and this information helps the clinician select the most appropriate technique for specimen collection.

Good-quality radiographs, including both left and right lateral projections, should be evaluated. Primary pulmonary tumors can cause localized mass lesions (see Figs. 20-7 and 20-10) or the consolidation of an entire lobe (see Fig. 20-9, A). Tumor margins are often distinct but can be ill-defined as a result of associated inflammation and edema. Cavitation may be evident. Metastatic or multicentric disease results in a diffuse reticular, nodular, or reticulonodular interstitial pattern (see Fig. 20-8). In cats primary lung tumors often have a diffuse distribution by the time of presentation, and the radiographic pattern may be suggestive of bronchitis, edema, or pneumonia.

Pulmonary neoplasia is occasionally associated with hemorrhage, edema, inflammation, infection, or airway occlusion that can contribute to the formation of alveolar patterns and consolidation. Lymphadenopathy, pleural effusion, or pneumothorax can also be identified by radiography in some patients with neoplasia.

Nonneoplastic disease, including fungal infection, lung parasites, the aspiration of mineral oil, eosinophilic granulomatosis, atypical bacterial infections, and inactive lesions from previous disease, can produce similar radiographic abnormalities. Pulmonary specimens must be evaluated to

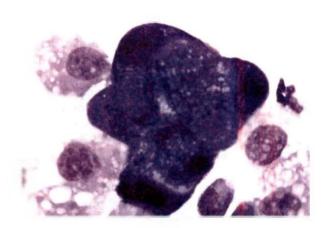

FIG 22-5

Bronchoalveolar lavage fluid from the dog whose lateral thoracic radiograph showing a severe, unstructured interstitial pattern is depicted in Fig. 20-8. Many clumps of deeply staining epithelial cells showing marked criteria of malignancy were seen. One such clump is shown here. A diagnosis of carcinoma was made. Note that a cytologic diagnosis of carcinoma should not be made if there is concurrent inflammation. The surrounding lighter-staining cells are alveolar macrophages, the normal predominant cell type in bronchoalveolar lavage fluid.

establish a diagnosis. Tracheal wash fluid cytology rarely results in a definitive diagnosis. It is generally necessary to evaluate lung aspirates, bronchoalveolar lavage fluid, or lung biopsy specimens.

It may be appropriate to delay the collection of pulmonary specimens in asymptomatic animals with multifocal disease or animals with significant unrelated problems. Rather, radiographs are obtained again in 4 to 6 weeks to document the progression of lesions. Such delay is never recommended in dogs or cats with potentially resectable disease.

The confirmation of malignant neoplasia in other organs in conjunction with typical thoracic radiographic abnormalities is often adequate for making a presumptive diagnosis of pulmonary metastases. Overinterpretation of subtle radiographic lesions should be avoided. Conversely, the absence of radiographic changes does not eliminate the possibility of metastatic disease.

Evaluation of the thorax by computed tomography should be considered in patients with known or suspected neoplasia. Computed tomography is much more sensitive than thoracic radiography in the detection of metastatic disease (see Chapter 20). In patients with localized disease for whom surgical excision is being planned, computed tomography provides more detailed anatomic information regarding the involvement of adjacent structures and is also more accurate in identifying involvement of tracheobronchial lymph nodes, compared with radiography (Paoloni et al., 2006).

#### **Treatment**

Solitary pulmonary tumors are treated by surgical resection. To obtain clear margins, usually the entire lung lobe that is involved must be excised. Lymph node biopsy specimens, as well as biopsy specimens from any grossly abnormal lung, are obtained for histologic analysis.

In animals with a large mass lesion, respiratory signs may abate after excision, even if metastatic lesions are present throughout the lungs. If the lesions cannot be removed surgically, chemotherapy can be attempted (see Chapter 77). No protocol is uniformly effective for the treatment of primary lung tumors.

Metastatic neoplasms of the lungs are treated with chemotherapy. In most animals the initial protocol is determined by the expected sensitivity of the primary tumor. Unfortunately, metastatic neoplasms do not always have the same response to specific agents as the primary tumor.

Multicentric tumors are treated with standard chemotherapeutic protocols, regardless of whether the lungs are involved. Multicentric tumors are discussed in Chapter 79. Lymphomatoid granulomatosis is treated with chemotherapy designed to treat lymphoma (see Chapter 80).

#### **Prognosis**

The prognosis for animals with benign neoplasms is excellent, but these tumors are uncommon. The prognosis for animals with malignant neoplasia is potentially related to several variables, which include tumor histology, presence of regional lymph node involvement, and presence of clinical signs. Survival times of several years are possible after surgical excision. Ogilvie et al. (1989) reported that of 76 dogs with primary pulmonary adenocarcinoma, surgical excision resulted in remission (i.e., elimination of all macroscopic evidence of tumor) in 55 dogs. The median survival time of dogs that went into remission was 330 days, whereas the survival time in dogs that did not achieve remission was 28 days. At the completion of the study, 10 dogs remained alive. McNiel et al. (1997) found that the histologic score of the tumor, presence of clinical signs, and regional lymph node metastases were significantly associated with the prognosis in 67 dogs with primary lung tumors. Median survival times for dogs with and without clinical signs were 240 and 545 days, respectively. Median survival times for dogs with and without lymph node involvement were 26 and 452 days, respectively. Median survival times for dogs with papillary carcinoma were 495 days, compared with 44 days for dogs with other histologic tumor types. Survival times ranged from 0 to 1437 days. A report of 21 cats with primary lung tumors found a median survival time of 115 days after surgery (Hahn et al., 1998). Cats with moderately differentiated tumors had a median survival time of 698 days (range of 13 to 1526 days), whereas cats with poorly differentiated tumors had a median survival time of 75 days (range of 13 to 634 days). The prognosis for animals with multicentric neoplasms is not known to depend on the presence or absence of pulmonary involvement.

#### PULMONARY HYPERTENSION

#### Etiology

Increased pulmonary arterial pressure (i.e., pulmonary systolic pressure >30 mmHg) is called *pulmonary hypertension*. The diagnosis is most accurately made by direct pressure measurements via cardiac catheterization, a procedure rarely performed in dogs or cats. An estimation of pulmonary artery pressure can be made by Doppler echocardiography in patients with pulmonary or tricuspid valvular insufficiency (see Chapter 6). The increasing availability of this technology has increased awareness of the existence of pulmonary hypertension in veterinary medicine. Causes of pulmonary hypertension include obstruction to venous drainage as can occur with heart disease (see Chapter 6), increased pulmonary blood flow caused by congenital heart lesions (see Chapter 5), and increased pulmonary vascular resistance. Genetic factors may influence the occurrence of pulmonary hypertension in some individuals but not in others with the same disease. When no underlying disease can be identified to explain the hypertension, a clinical diagnosis of primary (idiopathic) pulmonary hypertension is made.

Pulmonary vascular resistance can be increased as a result of pulmonary thromboembolism (see p. 317) or heartworm disease (see Chapter 10). Vascular resistance can also be increased as a complication of chronic pulmonary parenchymal disease, such as canine chronic bronchitis (see p. 287) and idiopathic pulmonary fibrosis (see p. 312). A simplistic explanation for increased vascular resistance as a complication of pulmonary disease is the adaptive response of the lung to improve the matching of ventilation and perfusion  $(\dot{V}/\dot{Q})$  through hypoxic vasoconstriction. However, in people other factors are thought to contribute significantly to the development of hypertension associated with pulmonary disease, including endothelial dysfunction, vascular remodeling, and possibly thrombosis in situ.

#### Clinical Features and Diagnosis

Pulmonary hypertension is diagnosed more commonly in dogs than cats. Clinical signs include those of progressive hypoxemia and can be difficult to distinguish from any underlying cardiac or pulmonary disease. Signs of pulmonary hypertension include exercise intolerance, weakness, syncope, and respiratory distress. Physical examination may reveal a loud split S2 heart sound (see Chapter 6). Radiographic evidence of pulmonary hypertension may be present in severely affected patients and includes pulmonary artery enlargement and right-sided cardiomegaly. Radiographs are evaluated closely for underlying cardiopulmonary disease. The diagnosis of pulmonary hypertension is most often made through Doppler echocardiography. Use of this modality to estimate pulmonary artery pressure requires the presence of pulmonary or tricuspid regurgitation and a highly skilled echocardiographer.

#### **Treatment**

Pulmonary hypertension is best treated by identifying and aggressively managing the underlying disease process. In people pulmonary hypertension associated with chronic bronchitis is usually mild and not directly treated. Longterm oxygen therapy is often provided, but this treatment is rarely practical for veterinary patients. Direct treatment can be attempted in patients showing clinical signs of pulmonary hypertension if no underlying disease is identified or management fails to improve pulmonary arterial pressures. Unfortunately, little is known about the treatment of pulmonary hypertension in animals, and adverse consequences can occur through worsening of V/Q matching or other drugrelated side effects. Therefore careful monitoring of clinical signs and pulmonary artery pressures is indicated. The drug most commonly used to treat pulmonary hypertension in dogs is sildenafil citrate (Viagra, Pfizer), a phosphodiesterase V inhibitor that causes vasodilation through a nitric oxide pathway. Dosage and toxicity studies have not been published, but a dosage range between 0.5 and 2.7 mg/kg (median 1.9 mg/kg) orally every 8 to 24 hours has been reported (Bach et al., 2006). A dosage of 0.5 mg/kg orally every 12 hours can be used initially and increased to effect. Long-term anticoagulation with warfarin or heparin is often prescribed for people with primary pulmonary hypertension to prevent small thrombi formation. Its potential benefits for veterinary patients are not known (see the next section, on the treatment of pulmonary thromboembolism).

#### Prognosis

The prognosis for pulmonary hypertension is presumably influenced by the severity of hypertension, presence of clinical signs, and any underlying disease.

#### **PULMONARY THROMBOEMBOLISM**

The extensive low-pressure vascular system of the lungs is a common site for emboli to lodge. It is the first vascular bed through which thrombi from the systemic venous network or right ventricle pass. The respiratory signs can be profound and even fatal in dogs and cats. Hemorrhage, edema, and bronchoconstriction, in addition to the decreased blood flow, can contribute to the respiratory compromise. The attendant increased vascular resistance secondary to the physical obstruction by emboli and vasoconstriction results in pulmonary hypertension, which can ultimately lead to the development of right-sided heart failure.

Thromboemboli generally form as a result of disease in organs other than the lungs, and a search for the underlying cause of clot formation is therefore essential. Abnormalities predisposing to clot formation include venous stasis, turbulent blood flow, endothelial damage, and hypercoagulation. In addition to emboli originating from thrombi, emboli can consist of bacteria, parasites, neoplasia, or fat. Conditions that have been associated with the development of pulmo-

nary emboli, and the pages where they are discussed, are listed in Box 22-3. The remainder of this discussion is limited to pulmonary thromboembolism (PTE).

#### **Clinical Features**

In many instances, the predominant presenting sign of animals with PTE is peracute respiratory distress. Cardiovascular shock and sudden death can occur. As awareness of PTE has increased, the diagnosis is being made with greater frequency in patients with milder and more chronic signs of tachypnea or increased respiratory efforts. Historic or physical examination findings related to a potential underlying disease increase the index of suspicion for a diagnosis of PTE. A loud or split-second heart sound (see Chapter 1) may be heard on auscultation and is indicative of pulmonary hypertension. Crackles or wheezes are heard in occasional cases.

#### **Diagnosis**

Routine diagnostic methods do not provide information that can be used to make a definitive diagnosis of PTE. A high index of suspicion must be maintained because this disease is frequently overlooked. The diagnosis is suspected on the basis of clinical signs, thoracic radiography, arterial blood gas analysis, echocardiography, and clinicopathologic data. A definitive diagnosis requires spiral (helical) computed tomography, angiography, or nuclear perfusion scanning, but spiral (helical) computed tomography is becoming the routine modality for diagnosis in people.

PTE is suspected in dogs and cats with severe dyspnea of acute onset, particularly if there are minimal or no radiographic signs of respiratory disease. In many cases of PTE the lungs appear normal on thoracic radiographs in spite of the severe lower respiratory tract signs. When radiographic lesions occur, the caudal lobes are most often involved. Blunted pulmonary arteries, in some cases ending with focal

<sup>\*</sup> Discussions of these abnormalities can be found in the given chapters.

or wedge-shaped areas of interstitial or alveolar opacities resulting from the extravasation of blood or edema, may be present. Areas of lung without a blood supply can appear hyperlucent. Diffuse interstitial and alveolar opacities and right-sided heart enlargement can occur. Pleural effusion is present in some cases and is usually mild. Echocardiography may show secondary changes (e.g., right ventricular enlargement, increased pulmonary artery pressures), underlying disease (e.g., heartworm disease, primary cardiac disease), or residual thrombi.

Arterial blood gas analysis can show hypoxemia to be mild or profound. Tachypnea leads to hypoxepnia, except in severe cases, and the abnormal alveolar-arterial oxygen gradient (*A-a* gradient) supports the presence of a ventilation-perfusion disorder (see Chapter 20). A poor response to oxygen supplementation is supportive of a diagnosis of PTE.

Clinicopathologic evidence of a disease known to predispose animals to thromboemboli further heightens suspicion for this disorder. Unfortunately, measurements of clotting parameters are not helpful in making the diagnosis. In people measurement of circulating D-dimers (a degradation product of cross-linked fibrin) is used as an indicator of the likelihood of PTE. It is not considered a specific test, so its primary value has been in the elimination of PTE from the differential diagnoses. However, even a negative result can be misleading in certain disease states and in the presence of small subsegmental emboli.

Measurement of D-dimer concentrations is available for dogs through commercial laboratories. A study of 30 healthy dogs, 67 clinically ill dogs without evidence of thromboembolic disease, and 20 with thromboembolic disease provides some guidance for interpretation of results (Nelson et al., 2003). A D-dimer concentration of >500 ng/ml was able to predict the diagnosis of thromboembolic disease with 100% sensitivity but with a specificity of only 70% (i.e., having 30% false-positive results). A D-dimer concentration of >1000 ng/ml decreased the sensitivity of the result to 94% but increased the specificity of the result to 80%. A D-dimer concentration >2000 ng/ml decreased the sensitivity of the result to 36% but increased the specificity to 98.5%. Thus the degree of elevation in D-dimer concentration must be considered in conjunction with other clinical information.

Spiral (helical) computed tomography is commonly used in people to confirm a diagnosis of PTE and is being used increasingly to confirm the diagnosis in veterinary medicine. One limitation of thoracic computed tomography in dogs and especially cats is patient size. In addition, veterinary patients will not hold their breath. Patients must be anesthetized and positive pressure ventilation applied during scanning for maximal resolution. A high quality computed tomography scanner and an experienced radiologist are required for accurate interpretation.

Angiography can provide a definitive diagnosis of PTE. Sudden pruning of pulmonary arteries or intravascular filling defects and extravasation of dye are characteristic

findings. However, these changes may be apparent for only a few days after the event, so this test must be done early in the disease. Nuclear scans can provide evidence of PTE with minimal risk to the animal. Unfortunately, this technology is for the most part available only at academic institutions.

Pulmonary specimens for histopathologic evaluation are rarely collected, except at necropsy. However, evidence of embolism is not always found at necropsy because clots may dissolve rapidly after death. Therefore such tissue should be collected and preserved immediately after death. The extensive vascular network makes it impossible to evaluate all possible sites of embolism, and the characteristic lesions may also be missed.

#### **Treatment**

Shock therapy may be needed for patients in severe distress, including high doses of rapid-acting glucocorticoids (e.g., prednisolone sodium succinate, up to 10 mg/kg intravenously). Animals should also receive immediate oxygen therapy (see Chapter 27).

Animals with suspected hypercoagulability are likely to benefit from anticoagulant therapy. Large-scale clinical studies of the response of dogs or cats with PTE to anticoagulant therapy have not been published. Anticoagulant therapy is administered only to animals in which the diagnosis is highly probable. Dogs with heartworm disease suffering from postadulticide therapy reactions usually are not treated with anticoagulants (see Chapter 10). Potential surgical candidates should be treated with great caution. Clotting times must be monitored frequently to minimize the risk of severe hemorrhage. General guidelines for anticoagulant therapy are provided here. However, more complete descriptions of anticoagulant therapy are available in the literature, and a current pharmacology text should be consulted before anticoagulants are used.

Initially, heparin (200 to 300 U/kg subcutaneously q8h) is administered for anticoagulant therapy. The goal of heparin therapy is to maintain the partial thromboplastin time (PTT) at 1.5 to 2.5 times normal, which corresponds to approximately a 1.2 to 1.4 times increase above the normal activated clotting time (ACT). Clotting times are evaluated before and 2 hours after the administration of heparin, and the dosage is adjusted on the basis of the results.

Hemorrhage is a potential complication of heparin therapy. Protamine sulfate is a heparin antagonist that can be administered if bleeding is not adequately controlled after heparin treatment is discontinued. Some clinicians advocate gradually tapering the dosage of heparin over several days when discontinuing treatment to avoid rebound hypercoagulation.

Heparin can be administered by the owner at home, but long-term anticoagulation is usually maintained with oral warfarin. Animals receiving warfarin therapy require frequent monitoring, and dosage adjustments are common. The potential for drug interactions with all concurrent medications being administered must be considered. An initial dosage of 0.1 to 0.2 mg/kg by mouth every 24 hours is pre-

scribed for dogs, and a total of 0.5 mg every 24 hours is prescribed for most cats. The goal of therapy is to maintain a prothrombin time (PT) of 1.5 to 2 times normal or an international normalization ratio (INR) of 2.0 to 3.0. It appears that it is safer to use the INR than the PT for monitoring anticoagulation. The INR is calculated from the measured PT and corrects for the variable strength of the thromboplastin reagent used in the assay. The INR or the formula to calculate it can be obtained from the commercial laboratory or the supplier of in-office test kits. Heparin therapy can be discontinued once the desired prolongation has been reached. It may be possible to decrease the frequency of administration of oral warfarin to every 48 hours after several days of treatment.

Until the PT has stabilized, which takes a minimum of 5 days, clotting times are assessed daily. Subsequent examination of the animal and evaluation of clotting times are performed at least every 5 days, with the interval gradually increasing to every 4 to 6 weeks if consistent and favorable results are obtained.

Excessive hemorrhage is the primary complication of warfarin therapy. Plasma or vitamin K<sub>1</sub> (2 to 5 mg/kg q24h) can be used to treat uncontrollable hemorrhage. However, if vitamin K is used, further attempts at anticoagulation using warfarin cannot be made for several weeks.

The use of fibrinolytic agents for the treatment of PTE in animals has not been well established. Recombinant tissue plasminogen activator has shown promise because it acts locally at sites of fibrin deposition.

Because of the serious problems and limitations associated with anticoagulant therapy, eliminating the predisposing problem must be a major priority.

#### **Prevention**

No methods of preventing PTE in at-risk patients have been objectively studied in veterinary medicine. Treatments that have potential benefit include the long-term administration of low molecular weight heparin, aspirin, or clopidagrel. Aspirin for the prevention of PTE remains controversial because aspirin-induced alterations in local prostaglandin and leukotriene metabolism may be detrimental.

#### **Prognosis**

The prognosis depends on the severity of the respiratory signs and the ability to eliminate the underlying process. In general, a guarded prognosis is warranted.

#### **PULMONARY EDEMA**

#### **Etiology**

The same general mechanisms that cause edema elsewhere in the body cause edema in the pulmonary parenchyma. Major mechanisms are decreased plasma oncotic pressure, vascular overload, lymphatic obstruction, and increased vascular permeability. The disorders that can produce these problems are listed in Box 22-4.

#### Possible Causes of Pulmonary Edema

#### **Decreased Plasma Oncotic Pressure**

Hypoalbuminemia
Gastrointestinal loss
Glomerulopathy
Liver disease
latrogenic overhydration
Starvation

#### Vascular Overload

Cardiogenic Left-sided heart failure Left-to-right shunts Overhydration

#### **Lymphatic Obstruction (Rare)**

Neoplasia

#### **Increased Vascular Permeability**

Inhaled toxins
Smoke inhalation
Gastric acid aspiration
Oxygen toxicity
Drugs or toxins
Snake venom
Cisplatin in cats

Electrocution

Trauma Pulmonary

Multisystemic

Sepsis

Pancreatitis

Uremia

Disseminated intravascular coagulation Inflammation (infectious or noninfectious)\*

#### Miscellaneous Causes

Thromboembolism
Upper airway obstruction
Near-drowning
Neurogenic edema
Seizures
Head trauma

The fluid initially accumulates in the interstitium. However, because the interstitium is a small compartment, the alveoli are soon involved. When profound fluid accumulation occurs, even the airways become filled. Respiratory function is further affected as a result of the atelectasis and decreased compliance caused by compression of the alveoli and decreased concentrations of surfactant. Airway resistance increases as a result of the luminal narrowing of small bronchioles. Hypoxemia results from ventilation-perfusion abnormalities.

<sup>\*</sup>Inflammation is usually the prominent clinical abnormality, not edema.

#### **Clinical Features**

Animals with pulmonary edema are seen because of cough, tachypnea, respiratory distress, or signs of the inciting disease. Crackles are heard on auscultation, except in animals with mild or early disease. Blood-tinged froth may appear in the trachea, pharynx, or nares immediately preceding death from pulmonary edema. Respiratory signs can be peracute, as in acute respiratory distress syndrome (ARDS), or subacute, as in hypoalbuminemia. However, a prolonged history of respiratory signs (e.g., months) is not consistent with a diagnosis of edema. The list of differential diagnoses in Box 22-4 can often be greatly narrowed by obtaining a thorough history and performing a thorough physical examination.

#### Diagnosis

Pulmonary edema in most dogs and cats is based on typical radiographic changes in the lungs in conjunction with clinical evidence (from the history, physical examination, radiography, echocardiography, and serum biochemical analysis [particularly albumin concentration]) of a disease associated with pulmonary edema.

Early pulmonary edema assumes an interstitial pattern on radiographs, which progresses to become an alveolar pattern. In dogs edema caused by heart failure is generally more severe in the hilar region. In cats the increased opacities are more often patchy and unpredictable in their distribution. Edema resulting from increased vascular permeability tends to be most severe in the dorsocaudal lung regions.

Radiographs should be carefully examined for signs of heart disease, venous congestion, PTE, pleural effusion, and mass lesions. Echocardiography is helpful in identifying primary cardiac disease if the clinical signs and radiographic findings are ambiguous.

Decreased oncotic pressure can be identified by the serum albumin concentration. Concentrations less than 1 g/dl are usually required before decreased oncotic pressure is considered to be the sole cause of the pulmonary edema. Pulmonary edema resulting purely from hypoalbuminemia is probably rare. In many animals volume overload or vasculitis is a contributing factor. Plasma protein quantitation using a refractometer can indirectly assess albumin concentration in emergency situations.

Vascular permeability edema, or noncardiogenic pulmonary edema, can result in the full range of compromise, from minimal clinical signs that spontaneously resolve to the frequently fatal, fulminant process of ARDS. ARDS, or "shock lung," describes a syndrome of acute, rapidly progressive pulmonary edema. In a review of 19 dogs with ARDS by Parent et al. (1996), the time of onset of dyspnea ranged from 0.5 to 48 hours (mean 4.5 hours) before admission, and the duration of dyspnea before death in dogs not mechanically ventilated ranged from 8 to 76 hours (mean 16 hours).

Pulmonary specimens from patients with vascular permeability edema are not cytologically unique, showing a predominantly neutrophilic response. Arterial blood gas analysis and pulse oximetry in dogs and cats with pulmonary edema are useful in selecting and monitoring therapy. Hypoxemia is present, usually in conjunction with hypoxapnia and a widened *A-a* gradient.

#### **Treatment**

It is easier for the body to prevent edema fluid from forming than it is to mobilize existing fluid. The initial management of pulmonary edema should be aggressive. Once the edema has resolved, the body's own compensatory mechanisms become more effective and the intensity of therapeutic interventions can often be decreased.

All animals with pulmonary edema are treated with cage rest and minimal stress. Dogs and cats with significant hypoxemia should receive oxygen therapy (see Chapter 27). Positive-pressure ventilation is required in severe cases. Methylxanthine bronchodilators (see pp. 290 and 296) may also be beneficial in some patients. They are mild diuretics and also decrease bronchospasms and possibly respiratory muscle fatigue. However, in some patients bronchodilators exacerbate ventilation:perfusion (V/Q) mismatching. The patient's response to bronchodilators should be carefully observed.

Furosemide is indicated for the treatment of most forms of edema but is not used in hypovolemic animals. Animals with hypovolemia actually require conservative fluid supplementation. If this is necessary to maintain the vascular volume in animals with cardiac impairment or decreased oncotic pressure, then positive inotropic agents or plasma infusions, respectively, are necessary.

Edema caused by hypoalbuminemia is treated with plasma or colloid infusions. However, it is not necessary for the plasma protein concentrations to reach normal levels for edema to decrease. Furosemide can be administered to more quickly mobilize the fluid from the lungs, but clinical dehydration and hypovolemia must be prevented. Diagnostic and therapeutic efforts are directed at the underlying disease.

The treatment of cardiogenic edema is discussed in Chapter 3.

Overhydration is treated by the discontinuation of fluid therapy. Furosemide is administered if respiratory compromise is present. If excessive volumes of fluid were not administered inadvertently, causes of fluid intolerance, such as oliguric renal failure, heart failure, and increased vascular permeability, must be sought.

Edema caused by increased vascular permeability is difficult to treat. In some cases, pulmonary compromise is mild and the edema transient. Routine supportive care with oxygen supplementation may be sufficient, but mechanical ventilation is often required. Any active underlying problem should be identified and corrected.

ARDS responds poorly to management. Ventilator therapy with positive end-expiratory pressure is indicated, and even with such aggressive support the mortality rate is high. Furosemide is generally ineffective in treating edema caused by increased vascular permeability, but because of limitations in our diagnostic capabilities, it is reasonable to include this

drug in the initial management of these patients. Glucocorticoids are of no clear benefit in these patients, but they are frequently given to animals with moderate to severe signs. Many novel therapics for ARDS have been studied in people, although to date none has been shown to be consistently effective in improving outcome. Studies are ongoing. Examples of such therapies include endotoxin blockers, inhibitors of specific inflammatory mediators, inhaled nitrous oxide, antioxidant drugs, and surfactant replacement.

#### **Prognosis**

The prognosis for an animal with pulmonary edema depends on the severity of the edema and the ability to eliminate or control the underlying problem. Aggressive management early in the course of edema formation improves the prognosis for an animal with any given disease. Animals with ARDS have a guarded to grave prognosis.

### CHAPTER

### Clinical Manifestations of the Pleural Cavity and Mediastinal Disease

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
PLEURAL EFFUSION: FLUID CLASSIFICATION AND
DIAGNOSTIC APPROACH

Transudates and Modified Transudates
Septic and Nonseptic Exudates
Chylous Effusions
Hemorrhagic Effusions
Effusions Caused by Neoplasia
PNEUMOTHORAX
MEDIASTINAL MASSES
PNEUMOMEDIASTINUM

#### GENERAL CONSIDERATIONS

Common abnormalities of the pleural cavity in the dog and cat include the accumulation of fluid (pleural effusion) or air (pneumothorax) in the pleural space. Mediastinal masses and pneumomediastinum are also discussed in this chapter. Respiratory signs caused by pleural disease result from interference with normal expansion of the lungs. Exercise intolerance is an early sign; overt respiratory distress ultimately occurs. Physical examination findings that assist in localizing the cause of respiratory compromise to the pleural space include increased respiratory rate and decreased lung sounds on auscultation (see Chapter 26). With increasing compromise, increased abdominal excursions during breathing may be seen. Breathing effort may be increased during inspiration relative to expiration, but this finding is not always obvious. In cats with mediastinal masses, decreased compressibility of the anterior thorax may be palpable. Thoracic radiography, thoracocentesis, or both are performed to confirm the presence of pleural space disease.

Pulmonary thromboembolism (PTE) can cause a pleural effusion. The effusion is generally mild and may be an exudate or a modified transudate. PTE should be considered as a diagnosis particularly in patients whose respiratory

efforts seem in excess of the volume of effusion (see Chapter 22).

### PLEURAL EFFUSION: FLUID CLASSIFICATION AND DIAGNOSTIC APPROACH

The presence of pleural effusion in a dog or cat is usually confirmed by thoracic radiography or thoracocentesis (see Chapter 24). In animals presented in respiratory distress with suspected pleural effusion, thoracocentesis is performed immediately to stabilize the animal's condition before radiographs are taken. Although thoracocentesis is more invasive than radiography, the potential therapeutic benefit of the procedure far outweighs the small risk of complications. Animals in stable condition at presentation can be evaluated initially with thoracic radiographs to confirm the presence and location of fluid before thoracocentesis is performed.

Ultrasonography is a valuable tool for the evaluation of patients with pleural effusion. If equipment is available on site, animals in critical condition can be examined ultrasonographically with minimal stress to confirm both the presence of fluid and direct needle placement for thoracocentesis. Ultrasonography is also useful in evaluating the thorax for the presence of mass lesions, hernias, and primary cardiac or pericardial disease. Because sound waves cannot pass through aerated lungs, any masses must be adjacent to the chest wall, heart, or diaphragm to be detected by ultrasound. The presence of pleural fluid facilitates the ultrasonographic evaluation of the chest. If the patient is stable, it is preferable to evaluate the thorax ultrasonographically before removing the pleural fluid.

Thoracic radiographs should be taken again after as much fluid or air as possible has been removed from the pleural space and the lungs have had time to reexpand. Full expansion of the lungs is required for accurate evaluation of the pulmonary parenchyma. The presence of fluid also obscures visibility of heart size and shape and mass lesions.

Cytologic analysis of pleural fluid obtained by thoracocentesis is indicated for the diagnostic evaluation of all

**TABLE 23-1** 

Diagnostic Approach in Dogs and Cats with Pleural Effusion Based on Fluid Type

FLUID TYPE	COMMON DISEASE	DIAGNOSTIC TESTS
Pure and modified transudates	Right-sided heart failure	Evaluate pulses, auscultation, ECG, thor rad, echo
	Pericardial disease	See right-sided heart failure
	Hypoalbuminemia (pure transudate)	Serum albumin concentrations
	Neoplasia	Thor rad and US, CT, thoracoscopy, thoracotomy
	Diaphragmatic hernia	Thor rad and US
Nonseptic exudates	Feline infectious peritonitis (FIP)	Pleural fluid cytology is generally sufficient. In questionable cases available tests are many, but none has shown good specificity for diagnosing FIP. Consider systemic evaluation, ophthalmoscopic examination, serum or fluid electrophoresis, coronavirus antibody titer, PCR of tissues or effusion (see Chapter 97)
	Neoplasia	See Neoplasia above
	Diaphragmatic hernia	See Diaphragmatic hernia above
	Lung lobe torsion	Thor rad and US, bronchoscopy, thoracotomy
Septic exudates	Pyothorax	Gram staining, aerobic and anaerobic cultures, serial thor rad
Chylous effusion	Chylothorax	See Box 25-1
Hemorrhagic effusion	Trauma	History
	Bleeding disorder	Systemic examination, coagulation tests (ACT, PT, PTT), platelet count
	Neoplasia	See Neoplasia above
	Lung lobe torsion	See Lung lobe tarsion above

ACT, Activated, clotting time; CT, computed tomography; ECG, electrocardiography; echo, echocardiography; PCR, polymerase chain reaction; PT, prothrombin time; PTT, partial thromboplastin time; thor rad, thoracic radiography; US, ultrasonography.

animals with pleural effusion. Measurement of the protein concentration and total nucleated cell count, as well as the qualitative assessment of individual cells, is essential for accurately classifying the fluid, formulating a diagnostic plan, and initiating appropriate therapy (Table 23-1).

Pleural fluid is classified as a transudate, modified transudate, or exudate on the basis of protein concentration and nucleated cell count. Further classification of fluid may be possible on the basis of other cytologic or biochemical features. Clinically useful fluid categories include septic exudate, chylous effusion, hemorrhagic effusion, and effusion caused by neoplasia. Although various types of fluid have typical gross appearances (Fig. 23-1), reliance on gross appearance alone will lead to the misclassification of fluid and missed diagnoses (through the failure to identify organisms or abnormal cell populations) in some cases. In addition to the inflammatory cell types in each cytologic category described in the subsequent sections, mesothelial cells are generally present and are often reactive.

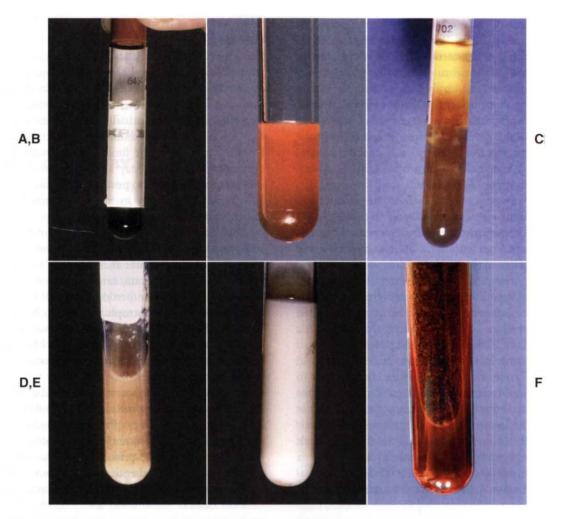

### TRANSUDATES AND MODIFIED TRANSUDATES

Pure transudates are fluids with low protein concentrations of less than 2.5 to 3 g/dl and low nucleated cell counts of less than 500 to 1000/µl. The primary cell types are mononuclear cells, composed of macrophages, lymphocytes, and mesothelial cells. Modified transudates have a slightly higher protein

concentration of up to 3.5 g/dl and nucleated cell counts of up to 5000/µl. The primary cell types include neutrophils as well as mononuclear cells.

Transudates and modified transudates form as a result of increased hydrostatic pressure, decreased plasma oncotic pressure, or a lymphatic obstruction. Increased hydrostatic pressure occurs in association with right-sided congestive heart failure or pericardial disease. Physical examination findings such as abnormal jugular pulses, gallop rhythms, arrhythmias, or murmurs support a diagnosis of heart disease. Heart sounds may be muffled in animals with pericardial effusions. Thoracic radiography (after fluid removal), electrocardiography, and echocardiography are indicated for cardiac evaluation (see Chapter 2).

Decreased plasma oncotic pressure is a result of hypoal-buminemia. Effusions secondary to hypoalbuminemia alone are pure transudates, having very low protein concentrations. Subcutaneous edema may be detected in dependent areas of the body. A decreased production of albumin causes hypoalbuminemia in patients with liver disease, and an increased loss of albumin causes it in patients with glomerulopathies or protein-losing enteropathies. The total plasma protein concentration shown by refractometry during the initial evaluation of the dog or cat can provide an early indication of hypoalbuminemia. Serum biochemical analysis provides an exact measurement of the albumin concentration. In general, albumin concentrations must be

#### FIG 23-1

Characteristic gross appearance of the various types of pleural effusion. Note that cytologic analysis should always be performed to ensure accurate classification of fluid and to avoid missing diagnostic organisms or neoplastic cells. **A,** Transudate. Fluid is nearly clear. **B,** Modified transudate. Fluid is slightly opaque and, in this example, redtinged. **C,** Nonseptic exudate. Fluid is more opaque. The fluid shown is from a cat with feline infectious peritonitis (FIP). FIP fluid is characteristically straw colored with grossly visible fibrin clots. **D,** Septic exudate. Fluid has a purulent appearance, with cellular debris gravitating toward the bottom of the tube. **E,** Chylous effusion. Fluid is milky white. **F,** Hemorrhagic effusion. Hemorrhagic effusions are bright to dark red. In this case, cytologic examination revealed filamentous organisms demonstrating the importance of cytologic analysis.

lower than 1 g/dl before transudation occurs caused only because of hypoalbuminemia.

Lymphatic obstruction can be caused by neoplasia and diaphragmatic hernias. Diaphragmatic hernias should be suspected in any animal with a history of trauma. The trauma may have been recent or may have occurred years ago. Although a modified transudate usually forms as a result of chronic diaphragmatic hernia, an exudative fluid can also be found. Diaphragmatic hernias are identified by radiography or ultrasonography. Occasionally, it is necessary to administer barium orally and perform an upper gastrointestinal series or to intraperitoneally administer water-soluble iodinated contrast media and perform peritoneography to confirm the presence of a diaphragmatic hernia. Normal imaging

findings do not entirely rule out the existence of a tear in the diaphragm, however.

Neoplasia must be considered as a differential diagnosis for patients with any type of effusion, although it is rare for a pure transudate to develop. (See the section on effusions caused by neoplasia for further discussion.)

#### SEPTIC AND NONSEPTIC EXUDATES

Exudates have a high protein concentration (greater than 3 g/dl) compared with that in transudates. Nucleated cell counts are also high (greater than 5000/µl). Cell types in *nonseptic exudates* include neutrophils, macrophages, eosinophils, and lymphocytes. The macrophages and lymphocytes may be activated, and typically the neutrophils are nonde-

generative. There is no evidence of organisms. Differential diagnoses in animals with nonseptic exudates include feline infectious peritonitis (FIP), neoplasia, chronic diaphragmatic hernia, lung lobe torsion, and resolving septic exudates. Prior treatment with antibiotics in animals with a septic effusion can alter the characteristics of the neutrophil population in the fluid, making them appear nondegenerative, and decrease the number of organisms present in the fluid to an undetectable level. Therefore pleural fluid analysis should be performed before treatment is initiated so that bacterial infection is not overlooked.

Cats with FIP can present with fever or chorioretinitis in addition to respiratory signs (see Chapter 97). The pleural fluid protein concentration is often very high in such animals, approaching serum concentrations. It is common to see fibrin strands or clots in the fluid. Careful cytologic evaluation of the fluid is essential to differentiate FIP fluid from exudates caused by pyothorax or malignant lymphoma. The evaluation of animals for diaphragmatic hernia was described in the previous section and is described for neoplasia in a following section (i.e., Effusion Caused by Neoplasia).

Spontaneous lung lobe torsions are most common in dogs with deep, narrow thoracic cavities. In addition to causing an effusion, torsions can be seen in dogs and cats secondary to pleural effusion. Underlying pulmonary disease resulting in lobe atelectasis can also contribute to the development of torsion. Torsion should be considered in animals with a preexisting effusion or pulmonary disease if their condition suddenly deteriorates. The effusion is often a nonseptic exudate, but it may be chylous or hemorrhagic. Signs of lung lobe torsion may be identified through thoracic radiography or ultrasonography (see Chapter 20). Bronchoscopy or thoracotomy is required to verify the condition in some animals.

Septic exudates often have extremely high nucleated cell counts (e.g., 50,000 to more than 100,000/µl), and degenerate neutrophils are the predominant cells. Bacteria can often be observed within neutrophils and macrophages as well as extracellularly (see Fig. 25-1). The fluid may have a foul odor. Septic exudates are diagnostic for pyothorax. Pyothorax can occur spontaneously, secondary to wounds that penetrate into the thoracic cavity through the chest wall or esophagus, secondary to migrating grass awns or other foreign bodies, or as an extension of bacterial pneumonia. Sterile technique should be used during thoracocentesis and chest tube placement in all animals with pleural effusion or pneumothorax to prevent iatrogenic infection.

Gram staining and both aerobic and anaerobic bacterial cultures with antibiotic sensitivity testing should be performed on the fluid. Culture and sensitivity testing provide valuable information that can be used for selecting appropriate antibiotics and monitoring therapy. Mixed bacterial infections are common. However, bacteria do not grow from cultures of all septic exudates, and results are not available for several days. Gram staining provides immediate information that can be used to help select antibiotics and is helpful in cases in which bacteria cannot be grown from the fluid.

#### CHYLOUS EFFUSIONS

Chylous effusion (chylothroax) results from the leakage of fluid from the thoracic duct, which carries lipid-rich lymph from the body. Such leakage can be idiopathic, congenital, or secondary to trauma, neoplasia, cardiac disease, pericardial disease, dirofilariasis, lung lobe torsion, or diaphragmatic hernia. Chyle is usually milky white and turbid (see Fig 23-1, E), largely as a result of chylomicrons that carry fats from the intestines. The fluid is occasionally blood tinged, although this finding may also be an artifact from prior thoracocentesis. It is also possible to obtain clear and colorless fluids, particularly in anorectic animals, but this is uncommon.

Chyle has the cytologic characteristics of a modified transudate or nonseptic exudate with moderate concentrations of protein, usually greater than 2.5 g/dl. The nucleated cell count is low to moderate, ranging from 400 to 10,000/µl. Early in the disease the predominant cell type is the small lymphocyte. A few neutrophils may also be present. With time, nondegenerative neutrophils become more predominant and there are fewer lymphocytes. Macrophages also increase in number with time, and plasma cells may be present.

A diagnosis of chylothorax is confirmed by measuring the concentrations of triglycerides in the pleural fluid and serum. Each specimen should be well mixed by the laboratory before a portion is analyzed because of the tendency for the lipid portion to rise to the surface. The triglyceride content in chyle is high compared with that in serum. Rarely, the test will need to be repeated after a meal in anorectic animals.

Most cases of chylothorax are idiopathic, but this diagnosis can be made only after the other disorders have been ruled out. Treatment is most likely to be successful if an underlying problem is identified and treated directly. (See Chapter 25 for a complete discussion of chylothorax.)

#### **HEMORRHAGIC EFFUSIONS**

Hemorrhagic effusions are grossly red as a result of the large red blood cell content. Hemorrhagic effusions have greater than 3 g/dl of protein and more than 1000 nucleated cells/ $\mu$ l, with a distribution similar to that of peripheral blood. Over time the numbers of neutrophils and macrophages increase. Hemorrhagic effusions (except those obtained immediately after bleeding into the thorax) are readily distinguished from the recovery of peripheral blood through traumatic thoracocentesis by several features: hemorrhagic effusions have erythrophagocytosis and an inflammatory response on cytologic evaluation, hemorrhagic effusions do not clot, and the packed cell volume (PCV) of hemorrhagic effusions is lower than that of peripheral blood.

Hypovolemia and anemia may contribute to the clinical signs of patients with hemothorax (see Chapter 26). Hemothorax can result from trauma, systemic bleeding disorders, neoplasia, and lung lobe torsion. Rarely, septic exudates are grossly hemorrhagic (see Fig 23-1, F) and are distinguished cytologically. Respiratory distress caused by hemothorax may be the only clinical sign in animals with some bleeding

disorders, including rodenticide intoxication. An activated clotting time and platelet count should be performed early in the evaluation of these animals, followed by more specific clotting tests (i.e., prothrombin time and partial thromboplastin time). Hemangiosarcoma of the heart or lungs is a common neoplastic cause of a hemorrhagic effusion, but malignant cells are rarely identified cytologically. Neoplastic effusions are discussed further in the next section.

#### EFFUSIONS CAUSED BY NEOPLASIA

Neoplasia within the thoracic cavity can result in most types of effusion (modified transudates, exudates, chylous effusion, or hemorrhagic effusion). Neoplasms may involve any of the intrathoracic structures, including the lungs, mediastinal tissues, pleura, heart, and lymph nodes. In some cases, neoplastic cells exfoliate from the tumor into the effusion, and an early diagnosis can be made through fluid cytology. This is often possible in patients with mediastinal lymphoma. Unfortunately, other than in cases of lymphoma, it can be difficult or impossible to establish a definitive diagnosis of neoplasia on the basis of cytologic findings in the pleural fluid alone. Inflammation can result in considerable hyperplastic changes of mesothelial cells that are easily confused with neoplastic cells. A cytologic diagnosis of neoplasia other than lymphoma should be made with extreme caution.

In the majority of cases, neoplastic cells are not present in the fluid or a cytologic diagnosis cannot be made. Thoracic radiography and ultrasonography should be performed to evaluate the thorax for evidence of neoplasia (see Chapter 24). Ultrasonography can be used to differentiate localized accumulations of fluid from soft tissue masses. If soft tissue masses are detected, aspirates or biopsy specimens are obtained for cytologic or histopathologic evaluation. A definitive diagnosis cannot be made on the basis of the radiograph findings or ultrasound images alone.

Diffuse neoplastic infiltration of the pleura and some masses cannot be seen with these imaging techniques. Repeated thoracic radiography, computed tomography, thoracoscopy, or surgical exploration may be necessary in such cases.

#### **PNEUMOTHORAX**

Pneumothorax is the accumulation of air in the pleural space. The diagnosis is confirmed by means of thoracic radiography. The pleural cavity is normally under negative pressure, which keeps the lungs expanded in health. However, if an opening forms between the pleural cavity and the atmosphere or the airways of the lungs, air is transferred into the pleural space because of this negative pressure. A tension pneumothorax occurs if a one-way valve is created by tissue at the site of leakage, such that air can enter into the pleural space during inspiration but cannot return to the airways or atmosphere during expiration. Increased intrapleural pressure and resultant respiratory distress occur quickly.

Leaks through the thoracic wall can occur after a traumatic injury or as a result of a faulty pleural drainage system. Air can also enter the thorax during abdominal surgery through a previously undetected diaphragmatic hernia. These causes are readily identified.

Pneumothorax resulting from pulmonary air can occur after blunt trauma to the chest (i.e., traumatic pneumothorax) or as a result of existing pulmonary lesions (i.e., spontaneous pneumothorax). Traumatic pneumothorax occurs frequently, and the history and physical examination findings allow this to be diagnosed. Pulmonary contusions are often present in these animals.

Spontaneous pneumothorax occurs when preexisting pulmonary lesions rupture. Cavitary lung diseases include blebs, bullae, and cysts, which can be congenital or idiopathic or result from prior trauma, chronic airway disease, or *Paragonimus* infection. Necrotic centers can develop in neoplasms, thromboembolized regions, abscesses, and granulomas involving the airways, and these can rupture, allowing air to escape into the pleural space. (See Chapter 20 for further discussion of cavitary lesions, and Chapter 25 for further discussion of spontaneous pneumothorax.)

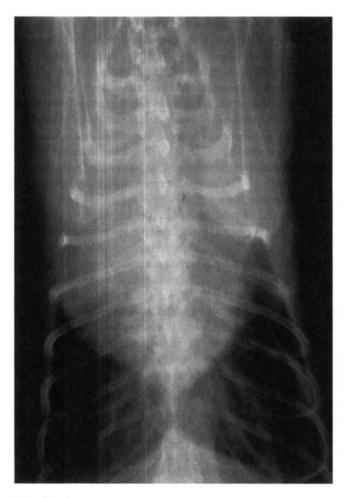

Dogs and cats with pneumothorax and a recent history of trauma are managed conservatively. Cage rest, the removal of accumulating air by periodic thoracocentesis or by chest tube, and radiographic monitoring are indicated. If abnormal radiographic opacities persist without improvement for more than several days in trauma patients, further diagnostic tests should be performed, as described in the section on spontaneous pneumothorax (see Chapter 25).

#### **MEDIASTINAL MASSES**

Mediastinal masses can cause inspiratory distress as a result of displacement of lung tissue by the mass itself or by the secondary pleural effusion that may develop. Additional clinical signs such as coughing, regurgitation, and facial edema may also be present. Neoplasia is the primary differential diagnosis. Lymphoma involving the mediastinum is common, particularly in cats. Other types of neoplasms include thymoma and rarely thyroid carcinoma, parathyroid carcinoma, and chemodectoma. Nonneoplastic mass lesions such as abscesses, granulomas, hematomas, and cysts are other possibilities.

Mediastinal masses in cats can often be palpated during gentle compression of the anterior thorax. Radiographically, mediastinal masses appear as soft tissue opacities in the anterior mediastinum (Fig. 23-2). However, it can be difficult to accurately identify a mediastinal mass if pleural fluid is present. Pleural fluid can both mimic the appearance of a mass and obscure its borders. Ultrasonography done before removal of the pleural fluid is helpful in identifying a mass and determining the extent to which surrounding structures are involved.

Thoracocentesis and fluid analysis should be performed in animals with pleural effusion. Lymphoma can frequently

**FIG 23-2**Ventrodorsal view of the thorax of a cat with an anterior mediastinal mass. Soft tissue opacity fills the anterior mediastinum and obscures the border of the heart.

be diagnosed through the identification of malignant cells in the effusion. Transthoracic fine-needle aspiration or biopsy can be performed to obtain specimens for microscopic evaluation of the mass itself. Aspiration cytology is generally performed initially, followed by biopsy if a cytologic diagnosis is not obtained. Transthoracic biopsy specimens can be obtained relatively safely, particularly if the lesion is solid rather than cystic. Ultrasonography can be helpful in determining the consistency of the mass and can also be used to guide biopsy. Alternatively, sites for sampling can be determined from two radiographic views of the thorax. The dorsal mediastinal area and heart should be avoided when obtaining biopsy samples. A study by Lana et al. (2006) demonstrated the usefulness of flow cytometry of mediastinal mass aspirates in differentiating lymphoma from thymoma in dogs.

Surgical exploration or thoracoscopy may be necessary to biopsy small lesions, cavitary lesions, and lesions adjacent to the heart or main blood vessels. Complete excision of the mass should be attempted at that time, unless lymphoma is diagnosed. (Specific recommendations for the management of dogs and cats with mediastinal neoplasia are given in Chapter 79)

#### **PNEUMOMEDIASTINUM**

Pneumomediastinum is identified radiographically. Subcutaneous emphysema or pneumothorax can occur concurrently or secondarily. Respiratory compromise most often results from pneumothorax. Mediastinal air commonly originates from rupture or tears in the trachea, bronchi, or alveoli. These leaks can occur as a result of bite wounds of the neck or sudden changes in intrathoracic pressure resulting from coughing, blunt trauma, or excessive respiratory efforts against obstructed airways. Potential iatrogenic causes include tracheal washing, tracheostomy, and endotracheal tube placement (usually caused by excessive endotracheal tube cuff pressure). Air can also enter the mediastinum through esophageal tears, generally resulting from foreign bodies.

Strict cage rest is indicated for animals with pneumomediastinum to facilitate natural sealing of the tear. If air continues to accumulate, causing respiratory compromise, bronchoscopy should be performed to identify tracheal or bronchial lacerations that may require surgical repair.

CHEST TUBES: INDICATIONS AND PLACEMENT
THORACOSCOPY AND THORACOTOMY

#### RADIOGRAPHY

#### PLEURAL CAVITY

The pleura surrounds each lung lobe and lines the thoracic cavity. It is not normally visible radiographically, and individual lung lobes cannot be distinguished. Abnormalities of the pleura and pleural cavity include pleural thickening, pleural effusion, and pneumothorax. The mediastinum in the dog and cat is not an effective barrier between the left and right side of the thorax, and effusion or pneumothorax is therefore usually bilateral.

#### **Pleural Thickening**

Pleural thickening results in a thin, fluid-dense line between lung lobes, where the pleura is perpendicular to the X-ray beam. These lines arc from the periphery toward the hilar region and are known as *pleural fissure lines*. The lines can occur as a result of prior pleural disease and subsequent fibrosis, mild active pleuritis, or low-volume pleural effusion. They can be an incidental finding in older dogs. Infiltration of the pleura with neoplastic cells generally results in effusion rather than thickening.

#### **Pleural Effusion**

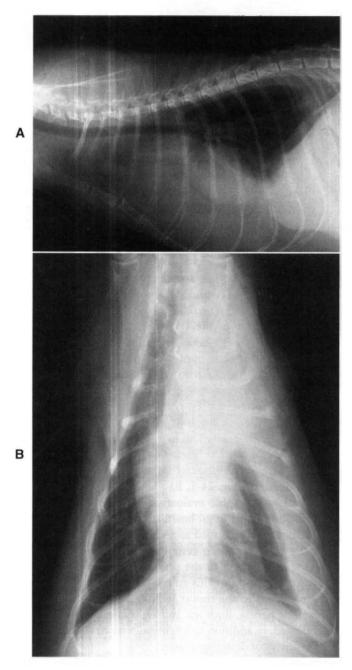

Pleural effusion is visible radiographically after about 50 to 100 ml has accumulated in the pleural cavity, depending on the size of the animal. An early effusion assumes the appear-

ance of pleural fissure lines and can be confused with pleural thickening. As fluid accumulates, the lung lobes retract and the lung lobe borders become rounded. Rounding of the caudodorsal angles of the caudal lung lobes is especially noticeable. The fluid silhouettes with the heart and diaphragm, obscuring their borders. The lungs float on top of the fluid, displacing the trachea dorsally and causing the illusion of a mediastinal mass or cardiomegaly (Fig. 24-1, A). As more fluid accumulates, the lung parenchyma appears abnormally dense as a result of incomplete expansion. Collapsed lobes should be examined carefully for evidence of torsion (see Chapter 20). Pockets of fluid accumulation or unilateral effusion indicates the possibility of concurrent pleural adhesions (Fig. 24-1, B).

Critical radiographic evaluation of intrathoracic structures, including the lungs, heart, diaphragm, and mediastinum, cannot be performed in animals with pleural effusion until the fluid has been removed. The interpretation of radiographs obtained in the presence of fluid is prone to error. An exception to this rule is the finding of gas-filled intestinal loops in the thorax, which is diagnostic for diaphragmatic hernia. Both left and right lateral views should be evaluated, in addition to a ventrodorsal view, to improve the sensitivity of detecting masses.

#### **Pneumothorax**

Pneumothorax is the presence of air in the pleural space. Air opacity without vessels or airways can be seen between the lung lobes and chest wall on radiographs. It may be necessary to carefully scrutinize the films using high intensity lighting to detect mild pneumothorax. As a greater volume of air accumulates in the pleural space, the lung parenchyma becomes more dense because of incomplete expansion, facilitating the radiographic diagnosis. The heart is generally elevated above the sternum, with air opacity apparent between these two structures (Fig. 24-2). Radiographs should be examined carefully for evidence of possible causes of the pneumothorax, such as cavitary lesions or rib fractures (indicating trauma). To accurately evaluate the pulmonary parenchyma, the air must be removed and the lungs allowed to expand. Cavitary lesions are not always apparent

**FIG 24-1 A,** Lateral thoracic view of a cat with pleural effusion. See text. **B,** Ventrodorsal view showing that the effusion is unilateral.

radiographically. Further evaluation for cavitary lesions in patients with spontaneous pneumothorax includes computed tomography.

#### **MEDIASTINUM**

The cranial and caudal mediastinum contains the heart and great vessels, esophagus, lymph nodes, and associated support structures. Radiographic abnormalities involving the mediastinum include pneumomediastinum, and alterations in size (e.g., mass lesions), displacement, and abnor-

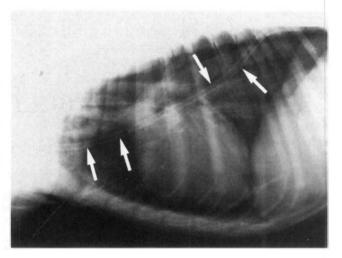

FIG 24-2

Lateral view of a dog with pneumothorax and pneumomediastinum. The pneumothorax is mild and is demonstrated by elevation of the heart above the sternum. When high-intensity lighting was placed behind the original radiographs, retraction of lung borders could also be seen. It is possible to visualize the outer wall of the trachea and major blood vessels in the anterior mediastinum because of the pneumomediastinum. A chest tube placed to stabilize the dog's condition is also visible (arrows).

malities involving the structures within the mediastinum (e.g., megaesophagus).

Pneumomediastinum is the accumulation of air in the mediastinum. If a pneumomediastinum is present, the outer wall of the trachea and the other cranial mediastinal structures, such as the esophagus, major branches of the aortic arch, and cranial vena cava, are contrasted against the air (see Fig. 24-2). These structures are not normally visible.

Abnormal soft tissue opacities can occur in the cranial mediastinum, although concurrent pleural effusion often obscures mass lesions. Localized lesions can represent neoplasia, abscesses, granulomas, or cysts (see Fig. 23-2). Less discrete disease can cause a general widening of the mediastinum that is seen to exceed the width of the vertebra on ventrodorsal views. Exudates, edema, hemorrhage, tumor infiltration, and fat can cause a widened mediastinum. Megaesophagus can often be observed in the cranial mediastinum, especially on lateral views.

The caudal vena cava and aorta are normally visible in the caudal mediastinum. The most common caudal mediastinal abnormalities are megaesophagus and diaphragmatic hernia. Megaesophagus is an important consideration in animals with respiratory signs because it is a common cause of aspiration pneumonia.

The mediastinum is normally located in the center of the thoracic cavity. An abnormal shift of the mediastinum is identified by a lateral change in the position of the heart on ventrodorsal or dorsoventral views. Atelectasis (i.e., lung lobe collapse), lobectomy, and adhesions of the mediastinum to the chest wall can all cause the mediastinum to shift

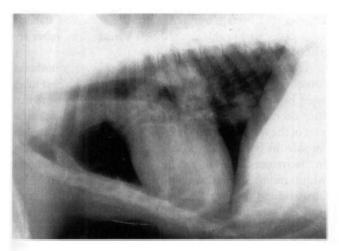

FIG 24-3

Lateral thoracic radiograph obtained in a dog with pulmonary neoplasia and sternal and hilar lymphadenopathy. The sternal node is the soft tissue opacity resting on the caudal half of the second sternebra. The hilar nodes are identified by the increased soft tissue opacity around the carina. Several discrete pulmonary nodules are also present.

toward the abnormality. Space-occupying lesions can cause the mediastinum to shift in the opposite direction.

The lymph nodes and heart are mediastinal structures but are considered separately to ensure a careful evaluation. The sternal nodes are located immediately dorsal to the sternum near the thoracic inlet at the level of the first to third sternebrae (Fig. 24-3). Enlargement is seen on lateral views and has the appearance of a discrete mass lesion. The hilar nodes are located at the heartbase around the carina. Enlargement is seen as a generalized increased soft tissue opacity in the perihilar region and is most easily seen on the lateral view. Common differential diagnoses for hilar lymphadenopathy are lymphoma and fungal infections (especially histoplasmosis). Other differential diagnoses include metastatic neoplasia, eosinophilic pulmonary granulomatosis, and mycobacterial infections. Any inflammatory disease can potentially cause lymphadenopathy. Other considerations in animals with an increased perihilar opacity on radiographs include atrial enlargement and heartbase tumors.

Evaluation of the heart is described in Chapters 1 and 2. Right-sided heart failure and pericardial effusion can cause pleural fluid accumulation.

#### **ULTRASONOGRAPHY**

Ultrasonography is indicated in the diagnostic evaluation of dogs and cats with pleural effusion to search for masses, diaphragmatic hernia, lung lobe torsion, and cardiac disease. Mediastinal masses, masses involving the pulmonary parenchyma adjacent to the body wall, and masses extending into the thorax from the body wall may be identified and their echogenicity evaluated. Ultrasonography can also be used to

guide aspiration needles or biopsy instruments to the lesion, although biopsies can be done safely only on solid masses. Ultrasonography is also useful for directing needle placement during thoracocentesis in animals with localized accumulations of pleural fluid. Air interferes with the sound waves, so structures surrounded by aerated lung cannot be examined.

#### **COMPUTED TOMOGRAPHY**

As discussed in Chapter 20, computed tomography is more sensitive than radiographs for evaluating the thorax. It is useful to determine the extent of mass lesions prior to thoracotomy and to increase the likelihood of localizing cavitary lesions in patients with spontaneous pneumothorax.

#### **THORACOCENTESIS**

Thoracocentesis is indicated for the collection of diagnostic specimens in dogs and cats with pleural effusion, for removal of pleural fluid or air to stabilize the condition of dogs and cats with impaired ventilation, and before radiographic evaluation of intrathoracic structures in dogs and cats with pleural fluid or air. Possible complications of thoracocentesis are pneumothorax caused by lung laceration, hemothorax, and iatrogenic pyothorax. Complications are extremely rare if careful technique is used.

Thoracocentesis is performed with the animal in lateral or sternal recumbency, depending on which position is less stressful. Fluid or air is usually present bilaterally throughout the pleural space and can be retrieved from the seventh intercostal space (ICS) by placing the needle approximately two thirds of the distance from the costochondral junction toward the spine. If initial attempts are unsuccessful, other sites are tried or the animal's position is changed. Fluid may be more successfully retrieved from gravity-dependent sites (i.e., closer to the costochondral junctions) and air from nondependent sites. Thoracic radiographs are useful in choosing sides for thoracocentesis in the event of unilateral effusions. Ultrasonography is useful for guiding needle placement in patients in which fluid collection proves difficult.

A local anesthetic can be administered at the site of thoracocentesis. Sedation is rarely required but may be useful for decreasing patient stress. The site is shaved and surgically prepared, and the procedure is performed using sterile technique. Most often, a butterfly catheter, three-way stopcock, and syringe are used. The removal of fluid or air by syringe is associated with movement of the syringe, and the tubing of the butterfly catheter prevents this movement from affecting the position of the needle within the thoracic cavity. Air and most fluids can be retrieved through a 21-gauge butterfly catheter. A larger needle may be required to collect extremely viscous fluids, such as fluid from feline infectious peritonitis or pyothorax. The three-way stopcock is attached

to the catheter to keep air from entering the thorax during emptying or changing of the syringe.

With the syringe snugly attached and the stopcock open between the catheter and syringe (closed to room air), the needle is advanced through the skin only. The needle and skin are then moved about two rib spaces to the actual collection site. This technique prevents air from entering the chest through the needle tract after the procedure (an unlikely scenario). The needle is then advanced into the thorax immediately in front of the rib to avoid the intercostal vessels and nerves. The needle is held with a hand resting on the chest wall so that it will not move relative to the respirations or movement of the animal. Slight negative pressure is applied to the catheter by the syringe so that entry into the pleural space is immediately identified by the recovery of fluid or air. Once the needle has entered the plcural space, the tip is aimed away from the lung by lowering the wings of the catheter toward the body wall. Ideally, the bevel of the needle should face toward the lungs.

An alternative to a butterfly catheter is an intravenous over-the-needle catheter. In large dogs a 31/4- or 51/4-inch (8- or 13-cm) 14- to 16-gauge catheter can be used. These catheters are soft and produce less trauma than butterfly catheters while in the pleural space and permit the animal to be repositioned or rolled to improve fluid or air removal. The longer length, compared with a butterfly needle, may be needed to reach the pleural space in large-breed or obese dogs. A few side holes can be added to the distal end of the catheter using a surgical blade and sterile technique to increase the sites where fluid can enter. The holes should be spaced far apart, should not take up more than one fifth of the circumference of the catheter, and should have no rough edges because the catheter might then break off in the animal during removal. Extension tubing and a three-way stopcock are attached to the catheter immediately after placement. A small skin incision, just slightly larger than the catheter, will facilitate placement. As with the butterfly catheter, slight negative pressure is maintained by syringe so that entry into the pleural space is immediately identified. The catheter tip is then directed cranially to allow positioning of the catheter between the lungs and chest wall, preventing trauma to the lung tissue.

After fluid specimens are saved for cytologic and microbiologic analysis, as much fluid or air as possible is removed, except in patients with acute hemothorax (see Chapter 26).

### CHEST TUBES: INDICATIONS AND PLACEMENT

Chest tube placement is indicated for the treatment of dogs and cats with pyothorax (see Chapter 25). Chest tubes are also indicated for the management of pneumothorax if air continues to accumulate despite multiple thoracocenteses. Chest tubes provide a means to prevent fluid and air from accumulating in the pleural space until the underlying cause of the pleural disorder resolves. If possible, needle thoraco-

centesis and therapy for shock are performed to stabilize dogs and cats in critical condition before chest tubes are placed.

The major complication of chest tubes is pneumothorax caused by a leak in the apparatus. Animals with chest tubes must be carefully monitored at all times to make sure that they do not disrupt the tubing connections, pull the tube part of the way out of the chest so that there are fenestrations outside the body wall, or bite through the tubing. Any leaks in the system can result in a life-threatening pneumothorax within minutes. If an animal with a chest tube must be left unattended, the tube should be clamped off close to the body wall and should be well protected by bandage material. Hemothorax, iatrogenic pyothorax, and pneumothorax caused by lung laceration can also occur, but these problems are generally prevented through the use of careful aseptic technique.

Pediatric chest tubes can be obtained from hospital supply companies. These tubes have multiple fenestrations, are calibrated along their length, and are radiopaque. For treating pyothorax, the tube should be as large as will fit between the ribs. The size of the tube is less critical for control of pneumothorax. Before placement the end of the tube is occluded with a syringe adapter, a three-way valve, and a hose clamp (Fig. 24-4, A).

Sterile technique is used during placement of the chest tube. In an animal with unilateral disease, the tube is placed in the involved side of the thorax. Either side can be used in an animal with bilateral disease. The lateral side of the animal over the caudal rib cage is shaved and surgically prepared. The animal is anesthetized or heavily sedated. If the animal is sedated, a local anesthetic is placed subcutaneously at the tenth ICS and within the subcutaneous tissues, intercostal muscles, and pleura at the seventh ICS. The dorsoventral orientation is one half to two thirds the distance from the costochondral junction to the thoracolumbar musculature. This distance should correspond to the level where the ribs are maximally bowed.

The length of tube to be advanced into the chest must be determined from thoracic radiographs or by external landmarks on the animal. The tube should extend from the tenth ICS to the first rib. The fenestrations in the tube must not extend outside the point of exit from the pleural cavity.

A stab incision is made through the skin at the tenth ICS. A purse-string suture is then placed around the opening but is not tied. Some chest tubes made for humans contain a stylet. Smaller chest tubes are inserted with the aid of curved hemostats. The tip of the tube is grasped with the tip of the hemostats with the tube parallel to the body of the clamps (see Fig. 24-4, *B*).

The tube, with the stylet or hemostats, is then tunneled subcutaneously from the tenth to the seventh ICS. If hemostats are used, the tips are directed away from the animal's body (see Fig. 24-4, C). Once the tip reaches the seventh ICS, the stylet or hemostats are raised perpendicular to the chest wall. The palm of the hand is placed over the end of the stylet or the hemostat handles, and the tube is thrust

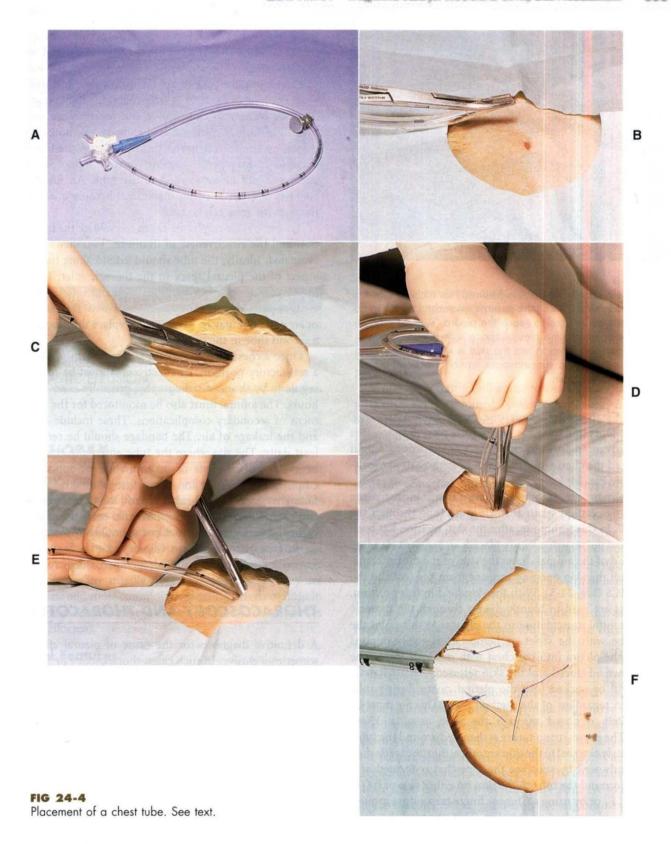

FIG 24-5

After an assistant pulls the skin forward, an incision can be made through the skin at the seventh intercostal space and blunt dissection is used to reach the pleura. A chest tube can be popped into the pleural space with minimal trauma to the underlying lung. When the skin is released, the tube will course through a subcutaneous tunnel to prevent air leaks around the tube.

through the body wall with one rapid motion (see Fig. 24-4, *D*). Once the tube has entered the pleural space, it is quickly advanced forward until the predetermined length has entered the chest while the stylet or hemostats are withdrawn (see Fig. 24-4, *E*).

An alternative technique can be used to minimize trauma to the lungs caused when thrusting the tube through the body wall. In this technique, after the skin incision has been made and a purse-string suture placed, an assistant standing at the head of the animal draws the skin of the thorax cranially to pull the skin opening forward from the tenth to the seventh ICS (Fig. 24-5). With the skin held in this position, hemostats are used to bluntly dissect through the thoracic and intercostal musculature to the pleura. At this point the chest tube with the stylet or hemostats is easily popped through the pleura into the chest with minimal force. The tube is then advanced and the skin released.

Air will be sucked into the pleural cavity during tube placement regardless of the method used. This air must be immediately removed through the tube using a 35-ml syringe. The purse-string suture is then tied around the tube. Immediately external to the skin entrance, the tube is attached to the body wall by suturing the tape that is formed as a butterfly around the tube to the skin on either side of it (see Fig. 24-4, F) or by using a Chinese finger trap suture around the tube and attached to the skin. This prevents the chest

tube from being withdrawn if tension is accidentally applied to the tubing. The opening in the skin is covered with a sterile sponge with antiseptic ointment. A light wrap is placed around the tube to hold it against the chest wall. The wrap must not be too tight. A wrap that is too tight can greatly decrease chest wall compliance and increase the work of breathing in these compromised animals. The hose clamp is placed on the tube between the animal and the three-way valve to further protect against pneumothorax whenever suction is not being applied to the tube. An Elizabethan collar is always placed on the animal because a single bite through the tube can be fatal.

Thoracic radiographs are taken to evaluate the tube position and the effectiveness of drainage. Two views must be evaluated. Ideally, the tube should extend along the ventral aspect of the pleural space to the thoracic inlet. The most important sign of adequate tube placement is the absence of areas of persistent fluid or air accumulation. If areas of fluid or air persist, it may be necessary to replace the tube or place a second tube in the opposite side.

Once a chest tube is in place and is determined to be in a satisfactory position, its effectiveness must be monitored regularly by thoracic radiography, generally every 24 to 48 hours. The animal must also be monitored for the development of secondary complications. These include infection and the leakage of air. The bandage should be removed at least daily. The site where the tube enters the skin should be evaluated for signs of inflammation or subcutaneous emphysema. The tube and skin sutures should be examined for signs of motion. The skin around the tube is kept clean, and a sterile sponge is replaced over the entry site of the tube before rebandaging. Stopcock ports should be protected with sterile caps when not in use. Gloves should be worn and the stopcock ports wiped with hydrogen peroxide before use.

#### THORACOSCOPY AND THORACOTOMY

A definitive diagnosis for the cause of pleural effusion is sometimes elusive. In such cases, thoracoscopy or thoracotomy may be necessary to allow visual assessment of the thoracic cavity and the collection of specimens for histologic and bacteriologic analysis. Mesotheliomas and pleural carcinomatosis are often diagnosed through these methods.

#### CHAPTER

# Disorders of the Pleural Cavity

#### CHAPTER OUTLINE

PYOTHORAX
CHYLOTHORAX
SPONTANEOUS PNEUMOTHORAX
NEOPLASTIC EFFUSION

#### **PYOTHORAX**

#### **Etiology**

Septic exudate in the pleural cavity is referred to as *pyothorax*. It is most often idiopathic in origin, particularly in cats. It can result from foreign bodies, puncture wounds through the chest wall, esophageal tears (usually from ingested foreign bodies), and extension of pulmonary infection. Thoracic foreign bodies are usually migrating grass awns. They are rare in cats and most common in sporting breeds of dogs in states where there is a large concentration of foxtail grasses (e.g., California).

#### **Clinical Features**

Dogs and cats with pyothorax have clinical signs referable to pleural effusion and abscess formation. Signs may be acute or chronic. Tachypnea, decreased lung sounds, and increased abdominal excursions are typical of pleural effusion. In addition, fever, lethargy, anorexia, and weight loss are common. Animals may be presented in septic shock or demonstrate signs of systemic inflammatory response syndrome.

#### **Diagnosis**

The diagnosis of pyothorax is made through thoracic radiography and the cytologic evaluation of pleural fluid. Thoracic radiographs are used to confirm the presence of pleural effusion and to determine whether the disease is localized, unilateral, or bilateral. In most animals fluid is present throughout the pleural space. The finding of a localized accumulation of fluid indicates the possible presence of pleural fibrosis, mass lesions, or lung lobe torsion. Thoracic

radiographs are taken again after removal of the fluid to evaluate the pulmonary parenchyma for evidence of underlying disease (e.g., bacterial pneumonia, foreign body) that may have caused the pyothorax. The identification of a septic exudate by pleural fluid analysis establishes the diagnosis of pyothorax.

Septic suppurative inflammation is a consistent finding in pleural fluid examined cytologically, except in animals that are receiving antibiotics (Fig. 25-1; see also Chapter 23). Pleural fluid is best evaluated by Gram staining and aerobic and anaerobic bacterial cultures. Anaerobes are usually present in the fluid, and in many dogs and cats, more than one type of bacteria are present. All of the types of bacteria involved may not grow in the laboratory in spite of cytologic evidence of their presence, possibly because of competition between organisms or an inhibitory effect of the exudative fluid. Organisms such as *Actinomyces* and *Nocardia* particularly do not grow well if specimens have been cultured using routine procedures. The absence of growth of bacteria does not rule out a diagnosis of pyothorax.

Evaluation of the patient's systemic status may reveal evidence of active inflammation, systemic inflammatory response syndrome, or sepsis.

#### **Treatment**

Medical therapy for pyothorax includes antibiotics, drainage of the pleural cavity, and appropriate supportive care (e.g., fluid therapy). At first, empirically selected antibiotics are administered intravenously. The results of Gram staining and culture and sensitivity testing are helpful in selecting antibiotics. Generally, anaerobes and Pasteurella (a common isolate from cats with pyothorax) are sensitive to amoxicillin-clavulanate. Other gram-negative organisms are often sensitive to amoxicillin-clavulanate, but their antibiotic sensitivities are unpredictable. Unfortunately, this drug is not available for intravenous administration. Ampicillin with sulbactam, a different -lactamase inhibitor, is an excellent substitute for intravenous use (22 mg/kg of ampicillin q8h). Other drugs that have good activity against anaerobic organisms are chloramphenicol, metronidazole, and clindamycin. If metronidazole or clindamycin is used, additional gram-

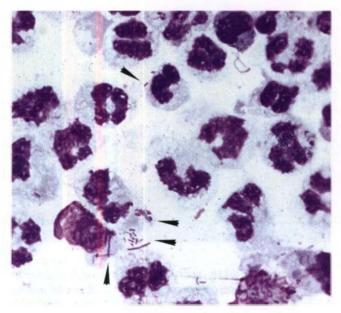

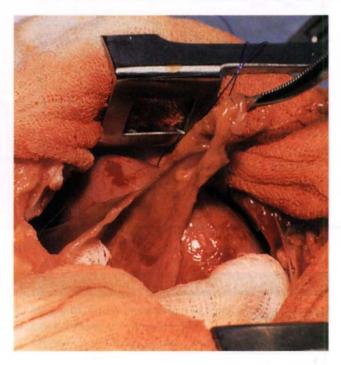

FIG 25-1
Cytologic preparation of a specimen of a pleural effusion from a cat with pyothorax. Degenerative neutrophils predominate, and intracellular and extracellular bacteria are prevalent (arrowheads). Both rods and cocci are seen.

negative coverage is necessary and is achieved by adding a fluoroquinolone or aminoglycoside antibiotic to the treatment. Addition of one of these antibiotics may also be necessary in patients receiving ampicillin with sulbactam that fail to show improvement in clinical condition, complete blood count (CBC), and fluid cytology within the first few days of treatment.

Oral antibiotics are used once significant improvement is noted, usually about the time of chest tube removal. Amoxicillin-clavulanate (20 to 25 mg/kg q8h) is used in patients that have responded to ampicillin with sulbactam. Oral antibiotic therapy is continued for an additional 4 to 6 weeks.

Drainage of the septic exudate is an essential part of the treatment of pyothorax. Although treatment with antibiotics alone often causes dramatic improvement in the animal's clinical condition initially, the signs generally recur, and complications of the prolonged infection, such as fibrosis or abscesses, are more likely (Fig. 25-2). Indwelling chest tubes provide the best drainage and can be used to keep the exudate from accumulating during the initial days of antibiotic therapy. Dogs and cats in critical condition at presentation are stabilized through the use of needle thoracocentesis and shock therapy before chest tube placement. Intermittent needle thoracocentesis is minimally effective for draining the pleural cavity and is not recommended for treatment unless the owner cannot afford the expense of chest tube management.

Chest tube placement and assessment of positioning are discussed in Chapter 24. Animals probably respond most rapidly to constant suctioning of the exudate from the chest, although intermittent suction is certainly adequate and often

Pleural fibrosis manifested by markedly thickened pleura seen during thoracotomy in a cat with chronic pyothorax. Treatment with antibiotics alone was attempted, and several weeks later the cat's condition deteriorated. Fibrosis was too extensive to allow for routine drainage with chest tubes. Surgical debridement, several lobectomies, drainage through surgically placed tubes, and long-term antibiotic therapy resulted in a cure.

more feasible. Constant suction is applied with a suction pump and collection unit. Disposable pediatric cage-side collection units (e.g., Thora-Seal III, Argyle, Sherwood Medical) are available through hospital supply companies. These units allow monitoring of collected fluid volume and adjustment of suction pressure. An initial suction pressure of 10 to 15 cm  $\rm H_2O$  is used, but more or less pressure may be necessary depending on the viscosity of the pleural fluid and the collapsibility of the tubes. The collection systems must be carefully monitored for the occurrence of leaks or malfunctions that could cause a fatal pneumothorax.

Intermittent suction by syringe is ideally performed every 2 hours for the first days of treatment, with arrangements made for drainage to continue during the night. Within a few days the volume of fluid produced will decrease, and the interval can then be lengthened. If such intensive care is not possible, an effort should still be made to empty the chest of fluid at least once late in the evening to minimize the accumulation of exudate overnight.

Lavage of the chest cavity is performed twice daily and consists of the removal of any fluid within the chest, followed by the slow infusion of warmed sterile saline solution into the chest. A volume of approximately 10 ml/kg of body weight is infused, but the infusion should be discontinued if any distress is noted. After this the animal is gently rolled

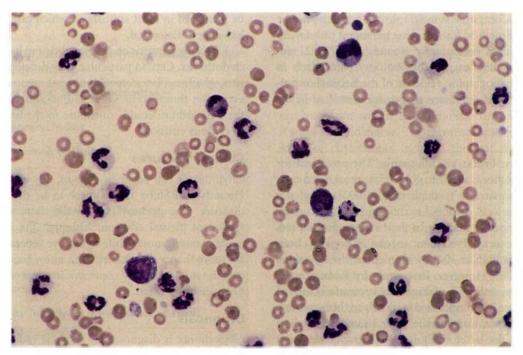

FIG 25-3
Cytologic preparation of a specimen of a pleural effusion from a cat being treated successfully for pyothorax with chest tube drainage and antibiotics. Compared with the fluid shown in Fig. 25-1, the nucleated cell count is low, the neutrophils are nondegenerative, organisms are not present, and mononuclear cells are appearing (Cytocentrifuge prep).

from side to side, and the fluid is removed. Sterile technique is used throughout the procedure. The volume recovered should be about 75% of the volume infused. If less fluid is retrieved, this may indicate that the chest tube is no longer providing adequate drainage and should be assessed by radiograph or ultrasonography. There is no obvious benefit from the addition of antibiotics, antiseptics, or enzymes to the lavage solution. The addition of heparin (1500 U/100 ml) to the lavage fluid may decrease fibrin formation.

All adapter ports connected to the chest tube should be covered with sterile caps when not in use. When accessing the ports, the clinician should wear gloves and remember to wipe the ports with hydrogen peroxide before use.

Thoracic radiographs are taken every 24 to 48 hours to ensure that the chest is being completely drained of fluid. Failure to monitor the effectiveness of drainage radiographically can lead to costly prolongation of the intensive care required for maintenance of the chest tube.

Serum electrolyte concentrations are also monitored. Many dogs and cats with pyothorax are dehydrated and anorectic at presentation and require intravenous fluid therapy. Supplementation of the intravenous fluid with potassium may be necessary.

The decision to discontinue drainage and remove the chest tube is based on the fluid volume and cytologic characteristics. The volume of fluid recovered should have decreased to less than 2 ml/kg/day. Slides of the fluid are prepared daily and evaluated cytologically. Bacteria should no longer be visible intracellularly or extracellularly. Neutro-

phils will persist but should no longer appear degenerative (Fig. 25-3). When these criteria have been met and no pockets of fluid are seen on thoracic radiographs, the chest tube is removed and the animal is monitored clinically for at least 24 hours for the development of pneumothorax or the recurrence of effusion. Thoracic radiographs can be taken to more sensitively evaluate the animal for these potential problems.

Thoracic radiographs are evaluated 1 week after removal of the chest tube and 1 week and 1 month after discontinuation of the antibiotic therapy. These radiographs are obtained so that a localized nidus of disease such as a foreign body or an abscess can be identified and also so that recurrence of a pyothorax can be detected before large volumes of pleural fluid accumulate. Such niduses are often invisible when large volumes of pleural fluid are present or while aggressive therapy is in progress.

Exploratory thoracotomy is indicated for the removal of a suspected nidus of infection and in those animals that do not respond to medical therapy. In the latter instance surgery may be necessary to remove fibrotic and diseased tissue or a foreign body. Failure to respond is suggested by the continued need for a chest tube for longer than 1 week after the start of appropriate antibiotic treatment and drainage, although reported cases that have undergone complete recovery after medical management have required drainage by chest tubes for longer periods. Furthermore, persistence of large pockets of fluid in spite of appropriate chest tube placement may necessitate the decision to perform a thora-

cotomy earlier. Computed tomography of the chest may be a more sensitive method for detecting persistent pulmonary lesions than thoracic radiography. Rooney et al. (2002) recommended consideration for thoracotomy particularly in dogs that have radiographic evidence of mediastinal or pulmonary lesions or if *Actinomyces* spp. are identified in the pleural fluid.

#### **Prognosis**

Most cases of pyothorax are idiopathic. The prognosis for animals with pyothorax is fair to good if it is recognized early and treated aggressively. Waddell et al. (2002) reported a survival rate for cats of 66%, excluding those that were euthanatized before treatment. In their report, 5 of 80 cats required thoracotomy. Treatment success in dogs has been reported to be as high as 100% with medical therapy alone (Piek et al., 2000). However, in a study by Rooney et al. (2002) of 26 dogs, only 25% of dogs were successfully treated medically whereas 78% responded favorably to thoracotomy. One possible explanation for the poor success of medical management in the latter study is the geographic location in a region of the country where grass awn migration is common.

Exploratory surgery is necessary to ensure complete resolution of the problem in dogs or cats with foreign bodies in the thoracic cavity. Radiolucent foreign bodies can be difficult to find, however, and the prognosis for pyothorax secondary to them is more guarded. Long-term complications of pyothorax such as pleural fibrosis and restrictive lung disease are uncommon.

#### **CHYLOTHORAX**

#### Etiology

Chylothorax is the accumulation of chyle within the thoracic cavity. The chyle originates from the thoracic duct, which carries triglyceride-rich fluid from the intestinal lymphatics and empties into the venous system in the anterior thorax. The fluid also contains lymphocytes, protein, and fat-soluble vitamins. Thoracic duct rupture after thoracic trauma can result in transient chylothorax. However, most cases are not the result of a ruptured duct. Possible causes of nontraumatic chylothorax include generalized lymphangiectasia, inflammation, and obstruction of lymphatic flow. Flow can be obstructed for physical reasons, such as neoplasia, or as a result of increased venous pressures.

Chylothorax can be categorized as congenital, traumatic, or nontraumatic. A congenital predisposition may exist in animals in which chylothorax develops later in life. Traumatic events that induce chylothorax can be surgical (e.g., thoracotomy) or nonsurgical (e.g., being hit by a car). Nontraumatic causes of chylothorax include neoplasia, particularly mediastinal lymphoma in cats; cardiomyopathy, dirofilariasis, pericardial disease, and other causes of right-sided heart failure; lung lobe torsion; diaphragmatic hernia; and systemic lymphangiectasia. No underlying disease can

be identified in most animals, in which case idiopathic chylothorax is diagnosed.

Fibrosing pleuritis and pericarditis can be associated with chylothorax. Cats, in particular, may develop fibrosing pleuritis, which can interfere with normal expansion of the lungs even after thoracocentesis. Inflammation and thickening of the pericardium could contribute to the further formation of chylous effusion.

#### **Clinical Features**

Chylothorax can occur in dogs or cats of any age. Afghan Hounds and Shiba Inus appear to be predisposed to the disorder. The primary clinical sign is respiratory distress typical of pleural effusion. Although the distress is often acute in onset, more subtle signs have generally been present for more than a month. Lethargy, anorexia, weight loss, and exercise intolerance are common. In some cases cough is the only presenting sign.

#### Diagnosis

Chylothorax is diagnosed by thoracic radiographs and the identification of chyle through cytologic and biochemical evaluation of pleural fluid obtained by thoracocentesis (see Chapter 23). Lymphopenia and panhypoproteinemia may be present in peripheral blood.

Once chylothorax has been diagnosed, further diagnostic tests are performed to identify potential underlying disease (Box 25-1). These tests include thoracic ultrasonography; echocardiography; microfilarial examination and adult antigen testing for heartworm disease; and, in cats, the measurement of thyroid hormone concentrations. Lymphangiography can be used to identify lymphangiectasia, sites of obstruction, and, rarely, sites of leakage from the thoracic duct. Lymphangiography is performed before the surgical ligation of lymphatics is attempted.

#### **Treatment**

Thoracocentesis and appropriate fluid therapy are used to stabilize dogs and cats with chylothorax, as needed, at presentation. Electrolyte abnormalities may be present. A concerted effort is made to identify any underlying cause of the chylothorax so that it can be directly treated. Elimination of the underlying problem may result in resolution of the chylothorax, although medical management (as described later for idiopathic chylothorax) is generally required for several weeks or even months. The exception is chylothorax of traumatic origin, which generally resolves within 1 to 2 weeks.

A routinely successful treatment for idiopathic chylothorax has not been established. Medical management is initially attempted because spontaneous remission occurs in some cases. In the absence of resolution with medical therapy, thoracic duct ligation and pericardectomy are recommended.

Medical management consists primarily of intermittent thoracocentesis and a low-fat diet. Thoracocentesis is performed as needed on the basis of the owner's observation of increased respiratory rate or effort or decreased activity or

appetite. Initially, thoracocentesis may need to be performed every 1 to 2 weeks. The interval between thoracocenteses will gradually lengthen if the chylothorax is responsive to medical management. Ultrasound guidance of the needle during thoracocentesis is especially helpful in removing pockets of chyle from the pleural cavity, and by increasing the effectiveness of drainage, it can prolong the interval between thoracocenteses.

A low-fat, nutritionally complete diet is fed (see Chapter 54). In humans medium-chain triglyceride oil is absorbed directly into the bloodstream, bypassing the lymphatics, and can be used as a fat supplement. Unfortunately, in dogs these triglycerides have been shown to enter the thoracic duct. Nevertheless, they can be added to the diet if additional calories are desired.

Medical management may be facilitated by the administration of rutin, a benzopyrone drug. Rutin has been used in humans for the treatment of lymphedema. It is thought to decrease the protein content of the effusion by affecting macrophage function. The resorption of effusion may thereby be enhanced and fibrosis of the pleura minimized. The drug is available over the counter at health food stores. A dosage of 50 to 100 mg/kg given orally every 8 hours is recommended.

Surgical management is considered if clinical signs have not improved within 2 to 3 months of medical therapy or if signs are intolerable. The recommended surgical management of chylothorax includes thoracic duct ligation and pericardectomy. Thoracic duct ligation is technically difficult and is ideally performed by an experienced surgeon. Multiple ligations of the thoracic duct and its collaterals are performed. The ducts are identified by lymphangiography before surgery, and lymphangiography is repeated after ligation to assess the success of ligation. Pericardectomy is recommended at the time of thoracic duct ligation and is associated with an improved outcome (Fossum et al., 2004).

Placement of pleuroperitoneal or pleurovenous shunts or mesh within the diaphragm to allow fluid to drain away from the pleural space has also been recommended for the management of chylothorax and should be considered if medical and surgical treatment are unsuccessful. These drainage procedures provide a route for the leaking chyle to reenter the circulation without producing the respiratory compromise associated with pleural effusion. Unfortunately, drains often become nonfunctional within months of placement.

#### **Prognosis**

The prognosis for chylothorax has generally been regarded as guarded unless the chylothorax was traumatically induced or the result of a reversible condition. However, a study by Fossum et al. (2004) indicated an overall success rate for thoracic duct ligation and pericardectomy of 100% in dogs and 90% in cats. It is not possible to predict the contribution of fibrosing pleuritis to clinical signs in cats with this complication. In cats with continued respiratory difficulties following resolution of effusion, decortication of the lung is considered.

#### SPONTANEOUS PNEUMOTHORAX

Spontaneous pneumothorax occurs when preexisting pulmonary cavitary lesions rupture. It is much less common than traumatic pneumothorax and occurs more often in dogs than cats. Rapid, profound respiratory distress occurs in the subset of animals in which a tension pneumothorax develops. Cavitary lesions can be congenital or idiopathic or result from prior trauma, chronic airway disease (e.g., idiopathic feline bronchitis), or Paragonimus infection. Necrotic centers can develop in neoplasms, thromboembolized regions (e.g., from dirofilariasis), abscesses, and granulomas involving the airways, and these can rupture, allowing air to escape into the pleural space. (See Chapter 20 for further discussion of cavitary lesions.)

Thoracocentesis is useful for initial stabilization of the animal's condition. If frequent thoracocentesis is needed to

Blebs can be seen in this intra-operative image of the lung of a dog that presented with spontaneous pneumothorax. The size of these blebs precluded their identification by either thoracic radiography or computed tomography. (Courtesy Dr. Guillaume Pierre Chanoit.)

control the pneumothorax, a chest tube is placed (see Chapter 24). Dogs and cats are evaluated for underlying disease with thoracic radiographs (repeated after full lung expansion), computed tomography of the thorax, multiple fecal examinations for *Paragonimus* ova (see Chapter 20), heartworm tests, and possibly tracheal wash fluid analysis or bronchoscopy. Computed tomography is much more sensitive for the identification of bullae or blebs and should be performed before thoracotomy. In a study by Au et al. (2006), thoracic radiography identified bullae or blebs in only 2 of 12 dogs with spontaneous pneumothorax whereas computed tomography was successful in identifying lesions in 9 of these dogs.

Patients with Paragonimus infections generally respond to medical treatment (See Chapter 22). Otherwise, surgical therapy is indicated for most animals. In a review of 21 cases, Holtsinger et al. (1993) found that most dogs with spontaneous pneumothorax managed medically with chest tubes and suction ultimately required surgery during the initial hospitalization or upon subsequent recurrence of pneumothorax to resolve the problem. Because unobserved recurrence of spontaneous pneumothorax can be fatal, conservative treatment is believed to carry more risk than surgery. Furthermore, a report of 64 cases by Puerto et al. (2002) showed that recurrence and mortality rates for dogs with spontaneous pneumothorax were lower in dogs that had surgery compared with dogs that were treated conservatively. A median sternotomy is generally recommended to allow exposure of all lung lobes because it is often not possible to localize all cavitary lesions preoperatively (Fig. 25-4). Abnormal tissue is evaluated histologically and microbiologically for a definitive diagnosis.

Conservative therapy consists of cage rest and chest tube placement with continuous suction (see the section on pyothorax). In large dogs a one-way Heimlich valve can be used rather than suction.

Regardless of the treatment used, recurrence is a possibility. Accurate diagnosis of the underlying lung disease and determination of the extent of involvement through a thoracotomy assist in determining the prognosis.

#### **NEOPLASTIC EFFUSION**

Neoplastic effusions resulting from mediastinal lymphoma are treated with radiation or chemotherapy (see Chapter 80). Effusions caused by mesothelioma or carcinoma of the pleural surfaces may respond to palliative therapy with intracavitary infusions of cisplatin or carboplatin (see Moore, 1992). Placement of pleuroperitoneal shunts or intermittent thoracocentesis to alleviate the degree of respiratory compromise can also be considered to prolong the life of patients that have no clinical signs beyond those resulting from the accumulation of pleural effusion.

# CHAPTER Emergency Management of Respiratory Distress

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS LARGE AIRWAY DISEASE

Extrathoracic (Upper) Airway Obstruction Intrathoracic Large Airway Obstruction PULMONARY PARENCHYMAL DISEASE PLEURAL SPACE DISEASE

#### GENERAL CONSIDERATIONS

Respiratory distress, or dyspnea, refers to an abnormally increased effort in breathing. Some authors prefer to use terms such as hyperpnea and increased respiratory effort in reference to this abnormality because dyspnea and distress imply feelings that cannot be determined with certainty in animals. Breathing difficulties are extremely stressful for people and are likely so for dogs and cats as well. Dyspnea is also physically exhausting to the animal as a whole and to the respiratory musculature specifically. Animals in respiratory distress at rest should be managed aggressively, and their clinical status should be frequently assessed.

A dog or cat in respiratory distress may show orthopnea, which is a difficulty in breathing in certain positions. Animals with orthopnea will assume a sitting or standing position with their elbows abducted and neck extended. Movement of the abdominal muscles that assist ventilation may be exaggerated. Cats normally have a minimal visible respiratory effort. Cats that show noticeable chest excursions or openmouth breathing are severely compromised. Cyanosis, in which normally pink mucous membranes are bluish, is a sign of severe hypoxemia and indicates that the increased respiratory effort is not sufficiently compensating for the degree of respiratory dysfunction. Pallor of the mucous membranes is a more common sign of acute hypoxemia resulting from respiratory disease than is cyanosis.

Respiratory distress caused by respiratory tract disease most commonly develops as a result of large airway obstruc-

tion, severe pulmonary parenchymal or vascular disease (i.e., pulmonary thromboembolism), pleural effusion, or pneumothorax. Respiratory distress can also occur as a result of primary cardiac disease causing decreased perfusion, pulmonary edema, or pleural effusion (see Chapter 1). In addition, noncardiopulmonary causes of hyperpnea must be considered in animals with apparent distress, including severe anemia, hypovolemia, acidosis, hyperthermia, and neurologic disease. Normal breath sounds may be increased in dogs and cats with these diseases, but crackles or wheezes are not expected.

A physical examination should be performed rapidly, paying particular attention to the breathing pattern, auscultatory abnormalities of the thorax and trachea, pulses, and mucous membrane color and perfusion. Attempts at stabilizing the animal's condition should then be made before initiating further diagnostic testing.

Dogs and cats in shock should be treated appropriately (see Chapter 30). Most animals in severe respiratory distress benefit from decreased stress and activity, placement in a cool environment, and oxygen supplementation. Cage rest is extremely important, and the least stressful method of oxygen supplementation should be used initially (see Chapter 27). An oxygen cage achieves both these goals, with the disadvantage that the animal is inaccessible. Sedation of the animal may be beneficial (Box 26-1). More specific therapy depends on the location and cause of the respiratory distress (Table 26-1).

#### LARGE AIRWAY DISEASE

Diseases of the large airways result in respiratory distress by obstructing the flow of air into the lungs. For the purposes of these discussions, extrathoracic large airways (otherwise known as *upper airways*) include the pharynx, larynx, and trachea proximal to the thoracic inlet; intrathoracic large airways include the trachea distal to the thoracic inlet and bronchi. Animals presenting in respiratory distress caused by large airway obstruction typically have a markedly increased respiratory effort with a minimally increased respiratory rate

BOX 26-1

Drugs Used to Decrease Stress in Animals with Respiratory Distress

#### Upper Airway Obstruction: Decreases Anxiety and Lessens Respiratory Efforts, Decreasing Negative Pressure within Upper Airways

Acepromazine

Dogs and cats

<sup>1,</sup> Slightly increased; 11, increased; 111, markedly increased; 1, decreased; N1, normal. Normal respiratory rates for dogs and cats at rest are  $\leq 20$ /min. In the hospital setting, rates of  $\leq 30$ /min are generally accepted as normal.

(see Table 26-1). Excursions of the chest may be increased (i.e., deep breaths are taken). Breath sounds are often increased.

#### EXTRATHORACIC (UPPER) AIRWAY OBSTRUCTION

Patients with extrathoracic (upper) airway obstruction typically have the greatest breathing effort during inspiration, which is generally prolonged relative to expiration. Stridor or stertor is usually heard, generally during inspiration. A history of voice change may be present with laryngeal disease.

Laryngeal paralysis and brachycephalic airway syndrome are the most common causes of upper airway obstruction (see Chapter 18). Other laryngeal and pharyngeal diseases are listed in Boxes 16-1 and 16-2. Severe tracheal collapse can result in extrathoracic or intrathoracic large airway obstruction or both. Rarely, other diseases of the extrathoracic

Patients with extrathoracic (upper) airway obstruction often present in acute respiratory distress because of a progressive worsening of airway obstruction after an exacerbating event. Medical intervention is nearly always successful in

breaking this cycle and stabilizing the patient's respiratory

status.

trachea, such as foreign body, stricture, neoplasia, granuloma, and hypoplasia, result in respiratory distress.

Patients with extrathoracic airway obstruction usually present with acute distress in spite of the chronic nature of most of these diseases because of a vicious cycle of increased respirations leading to increased obstruction, as described in Chapter 16. This cycle can almost always be broken with medical management (Fig. 26-1). The patient is sedated (see Box 26-1) and provided a cool, oxygen-rich environment (e.g., oxygen cage). For dogs with pharyngeal disease, primarily brachycephalic airway syndrome, morphine is given. Otherwise, acepromazine is used. Subjectively, dogs with brachycephalic airway syndrome seem to have more difficulty maintaining a patent airway when sedated with acepromazine compared with morphine. Short-acting corticosteroids are thought by some to be effective in decreasing local inflammation (e.g., dexamethasone, 0.1 mg/kg intravenously [IV], or prednisolone sodium succinate, up to 10 mg/kg IV).

In rare cases, sedation and oxygen supplementation will not resolve the respiratory distress and the obstruction must be physically bypassed. Placement of an endotracheal tube is generally effective. A short-acting anesthetic agent is administered. Long and narrow endotracheal tubes with stylets should be available to pass by large or deep obstructions. If an endotracheal tube cannot be placed, a transtracheal catheter can be inserted distal to the obstruction (see Chapter 27). If a tracheostomy tube is needed, it can then be placed under controlled, sterile conditions. It is rarely necessary to perform a nonsterile emergency tracheostomy.

#### INTRATHORACIC LARGE AIRWAY OBSTRUCTION

Respiratory distress caused by intrathoracic large airway obstruction is rare. Patients with intrathoracic large airway

obstruction typically have the greatest breathing effort during expiration, which is generally prolonged relative to inspiration. The most common cause of intrathoracic large airway obstruction is collapse of the mainstem bronchi and/or intrathoracic trachea (tracheobronchomalacia; see Chapter 21). A high-pitched, wheezing, coughlike sound is often heard during expiration in these patients, and crackles or wheezes may be auscultated. Other differential diagnoses include foreign body, advanced *Oslerus* infection, tracheal neoplasia, tracheal stricture, and bronchial compression by extreme hilar lymphadenopathy.

Sedation, oxygen supplementation, and minimizing stress as described for the management of upper airway obstruction are often effective in stabilizing these patients as well. High doses of hydrocodone or butorphenol will provide cough suppression and sedation (see Chapter 21). Dogs with chronic bronchitis may benefit from bronchodilators and corticosteroids.

#### PULMONARY PARENCHYMAL DISEASE

Diseases of the pulmonary parenchyma result in hypoxemia and respiratory distress through a variety of mechanisms, including the obstruction of small airways (obstructive lung disease; e.g., idiopathic feline bronchitis); decreased pulmonary compliance (restrictive lung disease, "stiff" lungs; e.g., pulmonary fibrosis); and interference with pulmonary circulation (e.g., pulmonary thromboembolism). The majority of patients with pulmonary parenchymal disease, such as those with pneumonias or pulmonary edema, develop hypoxemia through a combination of these mechanisms that contribute to V/Q mismatch (see Chapter 20), including airway obstruction and alveolar flooding, and decreased compliance.

Animals presenting in respiratory distress caused by pulmonary parenchymal disease typically have a markedly increased respiratory rate (see Table 26-1). Patients with primarily obstructive disease, usually cats with bronchial disease, may have prolonged expiration relative to inspiration with increased expiratory efforts. Expiratory wheezes are commonly auscultated. Patients with primarily restrictive disease, usually dogs with pulmonary fibrosis, may have prolonged inspiration relative to expiration and effortless expiration. Crackles are commonly auscultated. Occasionally, cats with severe bronchial disease will develop a restrictive breathing pattern in association with air trapping and hyperinflation of the lungs. Other patients, with a combination of these processes occurring, have increased efforts during both phases of respiration; shallow breathing; and crackles, wheezes, or increased breath sounds on auscultation. Differential diagnoses for dogs and cats with pulmonary disease are provided in Box 19-1.

Oxygen therapy is the treatment of choice for stabilizing dogs or cats with severe respiratory distress believed to be caused by pulmonary disease (see Chapter 27). Broncho-dilators, diuretics, or glucocorticoids can be considered

as additional treatments if oxygen therapy alone is not adequate.

Bronchodilators, such as short-acting theophyllines or  $\beta$ -agonists, are used if obstructive lung disease is suspected because they decrease bronchoconstriction. In combination with oxygen, they are the treatment of choice for cats with signs of bronchitis (see Chapter 21). Subcutaneous terbutaline (0.01 mg/kg, repeated in 5 to 10 minutes if necessary) or albuterol administered by metered dose inhaler are most often used in emergency situations. Bronchodilators are described in more detail in Chapter 21 (see pp. 290 and 296 and Box 21-2).

Diuretics, such as furosemide (2 mg/kg, administered intravenously), are indicated for the management of pulmonary edema. If edema is among the differential diagnoses of an unstable patient, a short trial of furosemide therapy is reasonable. However, potential complications of diuretic use resulting from volume contraction and dehydration should be taken into consideration. Continued use of diuretics is contraindicated in animals with exudative lung disease or bronchitis because systemic dehydration results in the drying of airways and airway secretions. The mucociliary clearance of airway secretions and contaminants is decreased, and airways are further obstructed with mucus plugs.

Glucocorticoids decrease inflammation. Rapid-acting formulations, such as prednisolone sodium succinate (up to 10 mg/kg, administered intravenously), are indicated for animals in severe respiratory distress caused by the following conditions: idiopathic feline bronchitis, thromboembolism after adulticide treatment for heartworms, allergic bronchitis, pulmonary parasitism, and respiratory failure soon after the initiation of treatment for pulmonary mycoses. Animals with other inflammatory diseases or acute respiratory distress syndrome may respond favorably to glucocorticoid administration. The potential negative effects of corticosteroids must be considered before their use. For example, the immunosuppressive effects of these drugs can result in the exacerbation of an infectious disease. Although the use of short-acting corticosteroids for the acute stabilization of such cases probably will not greatly interfere with appropriate antimicrobial therapy, long-acting agents and prolonged administration should be avoided. Glucocorticoid therapy potentially interferes with the results of future diagnostic tests, particularly if lymphoma is a differential diagnosis. Appropriate diagnostic tests are performed once the patient can tolerate the stress.

Broad-spectrum antibiotics are administered if there is evidence of sepsis (e.g., fever, neutrophilic leukocytosis with left shift and moderate to marked toxicity of neutrophils) or a high degree of suspicion of bacterial or aspiration pneumonia. Note that airway specimens (usually tracheal wash) should be obtained for culture if at all possible before initiating broad-spectrum antibiotics in order to confirm the diagnosis of bacterial infection and to obtain susceptibility data.

Specimens obtained after initiating antibiotics are often not diagnostic, even with continued progression of signs. However, airway sampling may not be possible in these unstable patients. If sepsis is suspected, blood and urine cultures may be useful. The diagnosis and treatment of bacterial and aspiration pneumonia are described in Chapter 22.

If the dog or cat does not respond to this management, it may be necessary to intubate the patient and institute positive-pressure ventilation (see Chapter 27) until a diagnosis can be established and specific therapy initiated.

#### PLEURAL SPACE DISEASE

Pleural space diseases cause respiratory distress by preventing normal lung expansion. They are similar mechanistically to restrictive lung disease. Animals presenting in respiratory distress as a result of pleural space disease typically have a markedly increased respiratory rate (see Table 26-1). Relatively increased inspiratory efforts may be noted but are not always obvious. Decreased lung sounds on auscultation distinguish patients with tachypnea caused by pleural space disease from patients with tachypnea caused by pulmonary parenchymal disease. Increased abdominal excursions during breathing may be noted.

Most patients in respiratory distress resulting from pleural space disease have pleural effusion or pneumothorax (see Chapter 23). Other differential diagnoses are diaphragmatic hernia and mediastinal masses. If pleural effusion or pneumothorax is suspected to be causing respiratory distress, needle thoracocentesis (see Chapter 24) should be performed immediately before further diagnostic testing is performed or any drugs are administered. Oxygen can be provided by mask while the procedure is performed, but successful drainage of the pleural space will quickly improve the animal's condition. Occasionally, emergency placement of a chest tube is necessary to evacuate rapidly accumulating air (see Chapter 24).

As much fluid or air should be removed as possible. The exception is in animals with acute hemothorax. Hemothorax is usually the result of trauma or rodenticide intoxication. The respiratory distress associated with hemothorax is often the result of acute blood loss rather than an inability to expand the lungs. In this situation, as little volume as is needed to stabilize the animal's condition is removed. The remainder will be reabsorbed (autotransfusion), to the benefit of the animal. Aggressive fluid therapy is indicated.

# CHAPTER

# Ancillary Therapy: Oxygen Supplementation and Ventilation

#### CHAPTER OUTLINE

**OXYGEN SUPPLEMENTATION** 

Oxygen Masks Oxygen Hoods

Nasal Catheters

Transtracheal Catheters

**Endotracheal Tubes** 

Tracheal Tubes

Oxygen Cages

VENTILATORY SUPPORT

#### **OXYGEN SUPPLEMENTATION**

Oxygen supplementation is generally indicated to maintain arterial blood oxygen pressures (PaO<sub>2</sub>) at more than 60 mm Hg. Oxygen supplementation is indicated in every dog or cat with signs of respiratory distress or labored breathing. Cyanosis is another clear indication. Whenever possible, the cause of hypoxemia should be identified and specific treatment initiated as well. Assisted ventilation is indicated for animals with an inadequate arterial oxygen concentration despite supplementation and for animals with arterial carbon dioxide pressures exceeding 60 mm Hg (see Chapter 20).

The inhaled concentration of oxygen can be supplemented by the administration of 100% oxygen by mask, hood, nasal catheter, transtracheal catheter, endotracheal tube, tracheal tube, or oxygen cage. Administration of oxygen by nasal catheter is very well suited to most practices.

When administering 100% oxygen to an animal, the clinician must consider the anhydrous nature of pure oxygen and the toxic effects of oxygen in a high concentration. Because oxygen from tanks contains no water, drying of the airways can occur quickly, particularly if the nasal cavity has been completely bypassed by catheters or tubes. All animals with respiratory tract diseases should be systemically hydrated. Moisture must be added to the airways of animals receiving oxygen by catheter or tube for longer than a few hours. Ven-

tilators designed for long-term use have a heated humidifier incorporated into their design. Humidity exchange filters, which can also be attached to tracheal and endotracheal tubes, function by retaining moisture from exhaled air and adding it to inhaled air. These filters can support bacterial growth and must be replaced daily. Nebulization can also be used to add moisture to the airways. Less effective methods of hydration can be used if other options are not available, such as instillation of sterile 0.9% sodium chloride solution directly into tubes or catheters. Some water vapor can also be added to the oxygen by incorporating pass-over or bubble humidifiers in the system.

The inhalation of air with greater than 50% oxygen is toxic to the pulmonary epithelium. Pulmonary function deteriorates, and death can result. Air with greater than 50% oxygen is therefore not provided for longer than 12 hours. If higher concentrations are necessary to maintain adequate arterial oxygen concentrations, ventilatory support is initiated.

#### **OXYGEN MASKS**

Oxygen masks are useful for short-term supplementation. The animal experiences minimal stress, and manipulations such as venous catheter placement and thoracocentesis can be performed. A snug fit is desirable to decrease the volume of dead space, and a relatively high flow rate is necessary (Table 27-1). Sterile eye ointment is applied to prevent desiccation of the corneas.

#### **OXYGEN HOODS**

Oxygen hoods that can be placed over the animal's head are available. With some, the animals must be laterally recumbent and still, limiting the use of hoods to animals recovering from anesthesia, those that are severely depressed, and those that are heavily sedated (Fig. 27-1). Others are designed to completely surround the animal's head and are attached around the neck. One design is an adaptation of an Elizabethan collar (OxyHood, Jorgensen Laboratories, Inc.). In some situations oxygen hoods may be better tolerated than oxygen masks, and it may take less manpower to care for an animal for which one is being used than an animal with an

TABLE 27-1

Maximum Achievable Oxygen Concentrations and Associated Flow Rates for Various Methods of Supplementation

METHOD OF ADMINISTRATION	MAXIMUM OXYGEN CONCENTRATION (%)	FLOW RATE	
Mask	50-60	8-12 L/min	
Nasal catheter	50	6-8 L/min or 50-150 mL/kg/min	
Transtracheal catheter	30-40	1-2 L/min	
Endotracheal tube	100	0.2 L/kg/min	
Tracheal tube	100	0.2 L/kg/min	
Oxygen cage	60	2-3*

<sup>\*</sup> After cage is filled, flow is adjusted based on oxygen concentration as measured by oxygen sensor.

FIG 27-1

An oxygen hood can be used for recumbent animals as a substitute for an oxygen mask. In this patient oxygen is being delivered through an opening in the top of the hood, and the light blue opening that will accommodate standard anesthesia tubing is left open for circulation of air. Regardless of the method used to increase the oxygen in inspired air, a means for escape of expired CO<sub>2</sub> is essential. (Disposa-Hood, Utah Medical Products, Inc., Midvale, Utah.)

oxygen mask. A means for escape of exhaled air must always be provided to prevent the buildup of CO<sub>2</sub> within the hood.

#### **NASAL CATHETERS**

Nasal catheters can be used for long-term oxygen supplementation (Fig. 27-2). The animal is relatively free to move and is accessible for evaluation and treatment. Most animals tolerate the catheter well. Catheters can become obstructed

FIG 27-2

Dog with intranasal catheter in place for delivery of oxygen. The catheter is sutured to the muzzle less than 1 cm from its exit from the naris and is further anchored with sutures to the face so that it exits behind the animal's head. An Elizabethan collar is routinely used to prevent the animal from removing the catheter.

with nasal secretions, however. Soft red rubber or infant feeding tubes or polyurethane catheters can be used. Tube size is based on patient size. In general, a 3.5 to 5 French tube is used for cats, and a 5 to 8 French tube is used for dogs.

The method of placement has been described by Fitzpatrick et al. (1986). First, the length of tubing to be inserted into the nasal cavity is measured against the head of the animal. The tubing should reach the level of the carnassial tooth. Sedation is rarely necessary. A water-soluble lubricant or 0.2% lidocaine jelly is applied to the length of the catheter that will be within the nasal cavity. Next, 0.2% lidocaine is dripped gently into the nasal cavity through the naris with the animal's nose pointed upward. The catheter is then passed through the naris, initially aimed dorsomedially

through the naris, then immediately ventromedially. Once the correct length of catheter has been inserted, it is gently bent beneath the lateral cartilage and sutured to the muzzle no farther than 1 cm caudal to the exit from the naris. The catheter can be further anchored to the face with sutures, traveling between the eyes to behind the animal's head. An Elizabethan collar is placed on the patient to prevent the animal from removing the catheter.

A sterile intravenous set can be connected to the catheter. The intravenous line can be attached to a half-filled bottle of sterile saline solution and positioned above the fluid level. Oxygen is then delivered through the bottle, below the fluid level, providing some moisture as the oxygen bubbles through the saline.

#### TRANSTRACHEAL CATHETERS

Oxygen can be administered through a jugular catheter placed with a sterile technique through the trachea. This approach is particularly useful for the emergency stabilization of animals with an upper airway obstruction. Branditz et al. (1989) have described a method for cardio-pulmonary resuscitation that can be performed by one person by administering oxygen at a high flow rate of 15 L/ min through a tracheal catheter. In this method a large jugular catheter is placed as described for transtracheal washing (see Chapter 20).

#### **ENDOTRACHEAL TUBES**

Endotracheal tubes are used to administer oxygen during surgical procedures and cardiopulmonary resuscitation. They can be used to bypass most upper airway obstructions for emergency stabilization. Pure oxygen can be administered for short periods. Longer supplementation requires the mixing of 100% oxygen with room air. Ventilation can be provided with a cuffed endotracheal tube. Trauma to the trachea is decreased through the use of high-volume, low-pressure cuffs and by inflating the cuff with the least amount of pressure necessary to create a seal. If positive-pressure ventilation is not being used, the cuff can remain deflated.

Because endotracheal tubes are not tolerated by alert animals, tracheal tubes are preferred for long-term management. Conscious animals in which endotracheal tubes are used must be given sedatives, analgesics, paralyzing agents, or a combination of these drugs. The combination of hydromorphone and diazepam is adequate in some animals. Pentobarbital, administered intravenously to effect, can be added if necessary. The combination of ketamine and valium may be safer for the initial intubation of patients that are hypoxemic. Following intubation and improvement in hypoxemia, morphine and pancuronium can be given.

The cuff should be deflated when possible to minimize tracheal damage. The tube must be cleaned periodically to remove secretions (see the recommendations for tracheal tube cleaning), and frequent flushing of the oral cavity is performed. Moisture must be added to the inspired gases, as previously discussed.

#### **TRACHEAL TUBES**

Tracheal tubes are placed through the tracheal rings and are readily tolerated by conscious animals. It is rare that an animal requires an emergency tracheostomy. Nearly all such animals can be stabilized using other techniques. Thus tracheal tubes can be placed using a careful, sterile surgical technique. Tracheal tubes are generally used for the management of animals with an upper airway obstruction. Room air often contains adequate oxygen for use in animals with an upper airway obstruction once the obstruction has been bypassed.

The tube itself should have a diameter nearly as wide as the tracheal lumen and a length of 5 to 10 rings. It is necessary to use high-volume, low-pressure cuffs to prevent tracheal damage and subsequent stricture. Double-lumen tubes are ideal for this method. The inner tube can be removed for cleaning and replaced easily. Single-lumen tubes also work and may be necessary in small animals.

Tracheal tubes are usually placed with the animal anesthetized with a short-acting agent. The trachea is exposed through a ventral midline incision made just beneath the larynx. The trachea is entered through an incision made a few rings below the cricoid cartilage, parallel to the trachea and perpendicular to the rings, and through just enough rings to allow passage of the tube. Either end of the incision can be widened with a small transverse incision. Stay sutures are placed on each side of the incision to facilitate initial placement of the tube as well as later replacement if the tube is accidentally or intentionally removed. The tube is then inserted into the opening. With minimal pressure on the airway, it is tied with gauze around the neck of the animal. Few or no sutures are used to close the incision to prevent the collection of air subcutaneously. A gauze sponge with a slit cut in it and coated with antiseptic ointment can be placed over the incision and around the tube.

The tube must be monitored for obstruction and cleaned. The inner tube of double-lumen tubes can be easily removed for this purpose. The tube is cleaned every 30 to 60 minutes initially, with the interval increased as less secretions accumulate. Sterile technique is used when handling the tubes, and they must be replaced if they become contaminated.

Single-lumen tubes are difficult to remove and replace safely for the first few days unless stay sutures are left in place. Periodic cleaning can be performed with the tube in place. Sterile saline solution is instilled into the tube for this purpose. To perform suctioning, a sterile urinary catheter with several openings at the end is attached to a suction unit and passed through the tube. The trachea and tracheal tube are then suctioned to remove secretions. Suctioning is performed for short intervals to allow the lungs to reinflate. Cleaning is performed every few hours initially, then less frequently if secretions are not accumulating.

A smaller tube can be used once the animal is able to oxygenate adequately with room air. The tube can be removed when the animal can oxygenate by breathing around a small

tube with the lumen obstructed. The incision is allowed to heal without suturing. The tip of the tube is cultured for bacteria.

Antibiotics are not administered prophylactically. Any existing infection or infections that occur during therapy are treated on the basis of culture and sensitivity information.

#### OXYGEN CAGES

Oxygen cages provide an oxygen-enriched environment with minimal stress to animals. However, the animal is isolated from direct contact, which can be a disadvantage. Other environmental factors, such as humidity, temperature, and carbon dioxide concentration, must be monitored and controlled or extreme stress and even death can occur. The animal is totally dependent on proper cage function. The ability of the cage to maintain the correct environment varies with the specific cage as well as with each animal. Commercial cages are available for veterinary use. Incubators from human hospitals can be modified for small animals.

#### **VENTILATORY SUPPORT**

The purposes of ventilatory support are to decrease the retention of carbon dioxide and to improve oxygenation. Ventilatory support is labor intensive and associated with complications, however. It is used when other means of respiratory support are not adequate.

The retention of carbon dioxide, or hypercapnia, occurs in animals that are unable to ventilate adequately. Spontaneous ventilation can be impaired by neurologic dysfunction, such as that which occurs with severe head trauma, polyneuropathies, and some toxicities. Ventilatory support is recommended in such animals if the PacO<sub>7</sub> level increases to more than 60 mm Hg. Hypoventilation caused by a pleural effusion or pneumothorax is treated by removing the fluid or air, not by positive-pressure ventilation. Hypoventilation caused by an upper airway obstruction is treated by establishing a patent airway.

Animals with cerebral edema, usually caused by trauma, may benefit from ventilatory support to maintain the PaCO<sub>2</sub> within 20 to 30 mm Hg. The resultant decrease in blood flow to the brain may decrease the total intracranial volume, thereby decreasing pressure on the brain.

Animals with severe lung disease may be unable to maintain adequate oxygenation without ventilatory support. Positive-pressure ventilation is routinely necessary for the management of patients with acute respiratory distress syndrome (ARDS; see Chapter 22, p. 319). As previously noted, the long-term administration of air with an oxygen concentration greater than 50% results in serious lung damage. If the PaO<sub>2</sub> cannot be maintained at greater than 60 mm Hg without excessive oxygen supplementation, ventilatory support is indicated.

The delivery of air by positive pressure is different from the normal inhalation of air by negative pressure. With positive pressure, the distribution of ventilation within the lungs is altered. The intrathoracic pressure increases each time the lungs are filled with air, which results in decreased venous return to the heart. Along with other effects, systemic hypotension results and can be severe enough to cause acute renal failure. Compliance of the lungs also decreases over time in animals receiving positive-pressure ventilation. As the lungs become stiffer, greater pressures are necessary to expand them. Careful monitoring of animals is essential during ventilation. Important variables to monitor include blood gas values, compliance, mucous membrane color, capillary refill time, pulse quality, arterial blood pressure, central venous pressure, lung sounds, and urine output. The extensive nursing care and monitoring required for these patients usually limit the use of long-term ventilatory support to large referral hospitals.

#### DYSPHAGIA, HALITOSIS, AND DROOLING

Dysphagia, halitosis, and drooling may co-exist in many animals with oral disease. Dysphagia (i.e., difficulty in eating) usually results from oral pain, masses, foreign objects, trauma, neuromuscular dysfunction, or a combination of these (Box 28-1). Halitosis typically signifies an abnormal bacterial proliferation secondary to tissue necrosis, tartar, periodontitis, or the oral or esophageal retention of food (Box 28-2). Drooling occurs because animals are unable to or are in too much pain to swallow (i.e., pseudoptyalism). Excessive salivation is usually due to nausea; animals that are not nauseated rarely produce excessive saliva (Box 28-3). Although any disease causing dysphagia may have an acute

onset, the clinician usually should first consider foreign objects or trauma as the cause in such an animal. The environment and vaccination history should also be assessed to determine whether rabies is a possibility.

The next step is a thorough oral, laryngeal, and cranial examination. This examination is often the most important diagnostic step because most problems producing oral pain can be partially or completely defined on the basis of physical examination findings. Ideally, this is done without chemical restraint to allow pain to be detected. However, the animal often must be anesthetized for the oral examination to be performed adequately. A search for anatomic abnormalities, inflammatory lesions, pain, and discomfort should always be made. If pain is found, the clinician should determine whether it occurs when the mouth is opened (e.g., retrobulbar inflammation), is associated with extraoral structures (e.g., muscles of mastication), or originates from the oral cavity. The clinician should also search for fractures, lacerations, crepitus, masses, enlarged lymph nodes, inflamed or ulcerated areas, draining tracts, loose teeth, excessive temporal muscle atrophy, inability to open the mouth while the animal is under anesthesia, and ocular problems (e.g., proptosis of the eye, inflammation, or strabismus suggestive of retrobulbar disease). If oral pain is apparent but cannot be localized, retrobulbar lesions, temporomandibular joint disease, and posterior pharyngeal lesions should be considered. A concurrent clinicopathologic evaluation may be useful, especially if oral examination findings indicate the presence of systemic disease (e.g., lingual necrosis resulting from uremia, chronic infection secondary to hyperadrenocorticism).

Biopsies should be done of mucosal lesions (e.g., masses, inflamed or ulcerated areas) and painful muscles of mastication. Masses that do not disrupt the mucosa, especially those on the midline and dorsal to the larynx, can be difficult to discern and are sometimes found only by careful digital palpation. Fine-needle aspiration and cytologic evaluation are reasonable first steps for the diagnosis of masses. Remember that fine-needle aspirates can only find disease; they cannot

#### Causes of Dysphagia

#### Oral Pain

Fractured bones or teeth

Trauma

Periodontitis or caries (especially cats)

Mandibular or maxillary osteomyelitis

Other causes

Retrobulbar abscess/inflammation

Various other abscesses or granulomas of the oral cavity Temporal-masseter myositis

Stomatitis, glossitis, pharyngitis, gingivitis, tonsillitis, or sialoadenitis

Immune-mediated disease

Feline viral rhinotracheitis, calicivirus, leukemia virus, or immunodeficiency virus

Lingual foreign objects, other foreign objects, or granulomas

Tooth root abscess

Uremia

Electrical cord burn

Miscellaneous causes

- Thallium
- Caustics

Pain associated with swallowing: esophageal stricture or esophagitis

#### Oral Mass

Tumor (malignant or benign) Eosinophilic granuloma Foreign object (oral, pharyngeal, or laryngeal) Retropharyngeal lymphadenomegally Inflammatory polyp of middle ear (primarily cats) Sialocele

#### **Oral Trauma**

Fractured bones (e.g., mandible, maxilla) Soft tissue laceration Hematoma

#### Neuromuscular Disease

Localized myasthenia Temporal-masseter myositis Temporomandibular joint disease Oral, pharyngeal, or cricopharyngeal dysfunction Cricopharyngeal achalasia

Tick paralysis Rabies Tetanus **Botulism** 

Various cranial nerve dysfunctions/CNS disease

BOX 28-2

#### Causes of Halitosis

#### **Bacterial Causes**

Food retained in the mouth

Anatomic defect allowing retention (exposed tooth roots, tumor, large ulcer)

Neuromuscular defect allowing retention (pharyngeal dysphagia)

Food retained in the esophagus

Tartar or periodontitis

Damaged oral tissue

Neoplasia/granuloma of mouth or esophagus Severe stomatitis/glossitis

#### **Eating Noxious Substances**

Necrotic or odoriferous food

exclude disease. Subtle masses or those dorsal to the larynx may sometimes be aspirated more accurately with ultrasonographic guidance. Multiple aspirations are usually done before a wedge or punch biopsy is performed.

Incisional biopsy specimens must include generous amounts of submucosal tissues. Many oral tumors cannot be diagnosed on the basis of findings from superficial biopsy specimens because of superficial necrosis and inflammation

BOX 28-3

#### Major Causes of Drooling

#### Ptyalism

Nausea

Hepatic encephalopathy (especially feline)

Seizure activity

Chemical or toxic stimulation of salivation (organophosphates, caustics, bitter drugs [e.g., atropine, metronidazole]] Behavior

Hyperthermia

Salivary gland hypersecretion

#### **Pseudoptyalism**

Oral pain, especially stomatitis, glossitis, gingivitis, pharyngitis, tonsillitis, or sialoadenitis (see Box 28-1)

Oral or pharyngeal dysphagia (see Box 28-1)

Facial nerve paralysis

caused by normal oral flora. Biopsies of these lesions are often not done aggressively because they bleed profusely and are hard to suture. The clinician should avoid major vessels (e.g., the palatine artery) and use silver nitrate to stop hemorrhage. It is better to have difficulty stopping hemorrhage after obtaining an adequate biopsy specimen than less difficulty stopping hemorrhage after obtaining a nondiagnostic specimen. If diffuse oral mucosal lesions are noted, search carefully for vesicles (e.g., pemphigus), and if these are found, remove them intact for histopathologic and immunofluorescent studies. If vesicles are not found, then at least two or three tissue samples representing a spectrum of new and old lesions should be submitted for analysis.

If oral examination findings are not helpful, plain oral and laryngeal radiographs are usually the best next steps. Oral cultures are rarely cost-effective because the normal oral flora makes interpretation of the results difficult. Even animals with severe halitosis or stomatitis secondary to bacterial infection rarely benefit from bacterial culture, unless there is a draining tract or abscess.

Halitosis often accompanies dysphagia, in which case it is usually more productive to determine the cause of the dysphagia. If halitosis occurs without dysphagia, the clinician should first be sure that the odor is abnormal and then check for the ingestion of odoriferous substances (e.g., feces). A thorough oral examination is still the most important test. Halitosis not attributable to an oropharyngeal lesion may be originating from the esophagus. Contrast-enhanced radiographs or esophagoscopy may reveal the presence of tumors or retained food secondary to stricture or weakness. If the history and oral examination are unrevealing except for the finding of mild-to-moderate tartar accumulation, the teeth should be cleaned to try to alleviate the problem.

Drooling is usually caused by nausea, oral pain, or dysphagia. The approach to the diagnosis of oral pain and dysphagia is described under the appropriate headings. Nausea is considered in the section on vomiting.

Dysphagic animals without demonstrable lesions or pain may have neuromuscular disease. Dysphagia of muscular origin usually results from atrophic myositis (see Chapter 31). The finding of swollen, painful temporal muscles suggests acute myositis. The combination of severe temporal-masseter muscle atrophy and difficulty opening the mouth (even when the animal is anesthetized) is suggestive of chronic temporal-masseter myositis. Biopsy of affected muscles is indicated, but the clinician must ensure that muscle tissue is retrieved; it is easy to obtain only fibrous scar tissue. It may help to have serum analyzed for antibodies to type 2M muscle fibers, a finding consistent with masticatory muscle myositis but not polymyopathy.

Neurogenic dysphagia is caused by disorders in the oral (i.e., also called *prehensile*), pharyngeal, or cricopharyngeal phases of swallowing (disorders of the latter two phases are discussed in the section on regurgitation). Rabies should always be considered, despite its relative rarity. After rabies is presumptively ruled out, cranial nerve deficits (especially deficits of cranial nerves V, VII, IX, XII) should be considered. Because the clinical signs vary depending on the nerve (or nerves) affected, a careful neurologic examination must be done.

Inability to pick up food or having food drop from the mouth while eating usually indicates a prehensile disorder. Dysphagia may be noticeable in dogs and cats with pharyngeal and cricopharyngeal dysfunction, but regurgitation is often more prominent. Dynamic contrast-enhanced radiographic studies (e.g., cinefluoroscopy or fluoroscopy) are best for detecting and defining neuromuscular dysphagia. If neuromuscular problems are seemingly ruled out by these radiographic studies, then anatomic lesions and occult causes of pain (e.g., soft tissue inflammation or infection) must be reconsidered.

### DISTINGUISHING REGURGITATION FROM VOMITING FROM EXPECTORATION

Regurgitation is the expulsion of material (i.e., food, water, saliva) from the mouth, pharynx, or esophagus. It must be differentiated from vomiting (the expulsion of material from the stomach and/or intestines) and expectoration (the expulsion of material from the respiratory tract). Historical and physical examination findings sometimes allow differentiation of these three (Table 28-1). Expectoration is generally associated with coughing at the time of the event. However, because dogs that cough and gag excessively may stimulate themselves to vomit as well, careful history taking is important. Animals that regurgitate and occasionally those that vomit may cough as a result of aspiration, but oral expulsion is not consistently correlated with coughing in these patients.

The criteria in Table 28-1 are only guidelines. Some animals that appear to be regurgitating are vomiting and vice

Aids to Differentiate Regurgitation from Vomiting\*

SIGN	REGURGITATION	VOMITING
Prodromal nausea†	No	Usually
Retching‡	No	Usuallý
Material produced		,
Food	<u>+</u>	±
Bile	No	±
Blood	± (undigested)	± (digested or undigested)
Amount of material	Any amount	Any amount
Time relative to eating	Anytime	Anytime
Distention of cervical esophagus	±	No
Dipstick analysis of material		
рH	≥7	≤5 or ≥8
Bile	No	<u>+</u>

<sup>\*</sup>These are guidelines that often help distinguish vomiting from regurgitation. However, occasional animals will require plain and/or contrast-enhanced radiographs to distinguish between the two. †May include salivation, licking lips, pacing, and an anxious expression. The owner may simply state that the animal is aware that it will soon "vomit."

<sup>‡</sup>These are usually forceful, vigorous abdominal contractions or dry heaves. This is not to be confused with gagging.

versa. If the clinician cannot distinguish between the two on the basis of the history and physical examination findings, he or she may use a urine dipstick to determine the pH and whether there is bilirubin in *freshly* "vomited" material. If the pH is 5 or less, the material has originated from the stomach and probably resulted from vomiting. If the pH is more than 7 and there is no evidence of bilirubin, this is most consistent with regurgitation. The presence of bilirubin indicates that the material has originated from the duodenum (i.e., vomiting). A positive finding of blood in the urine dipstick test is not useful.

If vomiting and regurgitation still cannot be distinguished, plain and/or contrast-enhanced radiographs will usually detect esophageal dysfunction. However, some esophageal disorders (e.g., hiatal hernia, partial stricture, partial or segmental motility defect) are easily missed unless a careful radiographic technique and/or fluoroscopy are used. Endoscopy is rarely required to detect esophageal lesions missed by imaging (e.g., esophagitis).

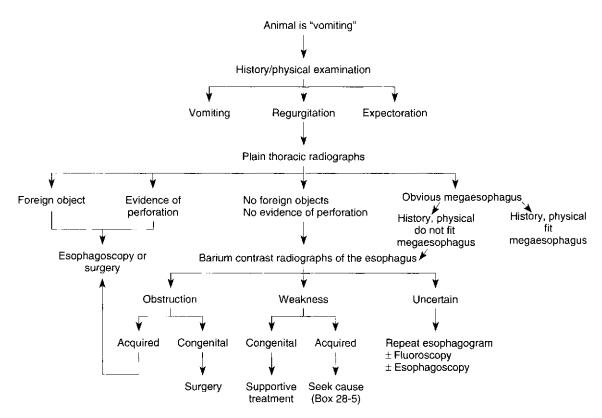

#### **REGURGITATION**

Once regurgitation is confirmed, the disease should be localized to the oral cavity/pharynx or esophagus (Fig. 28-1). The history, in combination with observation of the pet eating, should allow the clinician to detect evidence of dysphagia (e.g., undue stretching or flexing of the neck during swal-

lowing, repeated efforts at swallowing, food falling from the mouth during swallowing) if it is present. Some animals with dysphagia associated with neuromuscular disorders have more difficulty swallowing liquids than solid foods, probably because it is easier to aspirate liquids. Attempts to swallow water may produce coughing in these animals.

If a regurgitating animal is dysphagic, oral, pharyngeal, and cricopharyngeal dysfunctions should be considered; the latter two mimic each other. Fluoroscopic evaluation of swallowing during a barium meal is necessary to differentiate pharyngeal from cricopharyngeal dysfunction. If they are not accurately differentiated, inappropriate therapy may cause morbidity or mortality.

If the regurgitating animal is not dysphagic, esophageal dysfunction is most likely. The two main reasons for esophageal regurgitation are obstruction and muscular weakness. Plain thoracic radiographs, with or without barium contrast-enhancement, are the best tools for initially defining these problems. Fluoroscopy is often necessary in animals with a partial loss of peristalsis, segmental aperistalsis, gastroesophageal reflux, or sliding hiatal hernias. If the animal seems to be regurgitating but the contrast-enhanced radiographs fail to reveal esophageal dysfunction, either the assessment of regurgitation is wrong or there is occult disease (e.g., partial stricture of the esophagus, esophagitis, gastroesophageal reflux). Procedures involving the use of liquid barium sulfate may miss some lesions (e.g., partial strictures). Repeating contrast-enhanced esophagography using

**FIG 28-1**General diagnostic approach to regurgitation in the dog and cat.

#### Causes of Esophageal Obstruction

#### **Congenital Causes**

Vascular ring anomaly

Persistent fourth right aortic arch (most common type) Other vascular rings

Esophageal web (rare)

#### **Acquired Causes**

Foreign object Cicatrix/stricture

Neoplasia

Esophageal tumors

- Carcinoma
- Sarcoma caused by Spirocerca lupi
- · Leiomyoma of lower esophageal sphincter

Extraesophageal tumors

- Thyroid carcinoma
- Pulmonary carcinoma
- Mediastinal lymphosarcoma

Achalasia of the lower esophageal sphincter (very rare) Gastroesophageal intussusception (very rare)

barium plus food or performing esophagoscopy (or both) is appropriate in such patients.

Esophageal obstruction is principally caused by foreign objects and vascular anomalies, although cicatrix, tumors, and achalasia of the lower esophageal sphincter may also be responsible (Box 28-4). Obstruction should be characterized as congenital or acquired and as intraluminal, intramural, or extraesophageal. Congenital obstructions are usually extraesophageal vascular ring anomalies. Acquired intraluminal obstructions are usually caused by foreign objects or cicatrix secondary to esophagitis. The clinician should always determine whether animals with esophageal foreign objects also have a partial esophageal stricture that has predisposed them to the obstruction. Endoscopy may be both diagnostic and therapeutic in these animals; thoracotomy is seldom needed for the management of cicatrix or intraluminal foreign objects.

Esophageal weakness may be congenital or acquired. Congenital weakness is of uncertain cause, and further diagnostics are typically unfruitful. Acquired esophageal weakness usually results from an underlying neuromuscular problem. Although an underlying cause is infrequently diagnosed, finding one may lead to a permanent cure as opposed to supportive therapy, which only treats symptoms. A complete blood count (CBC), serum biochemistry profile, determination of serum antibody titers to acetylcholine receptors, an adrenocorticotropic hormone (ACTH)–stimulation test (see Chapter 53), and/or fecal examination for *Spirocerca lupi* ova are performed to look for causes of acquired esophageal weakness (Box 28-5). One may also consider searching for lead intoxication (nucleated red blood cells and basophilic stippling in the CBC, serum and urine lead concentra-

Tetanus

Lead poisoning

Canine distemper

Idiopathic

tions), canine distemper (retinal lesions), and neuropathy-myopathy (electromyography, nerve biopsy, muscle biopsy). Chagas' disease causes esophageal disease in people, but it is unknown whether it causes esophageal weakness in dogs.

Esophagoscopy may detect esophagitis or small lesions (e.g., partial strictures) that contrast-enhanced esophagrams do not reveal. If esophagitis is found, the clinician should look carefully for a cause (e.g., hiatal hernia, gastric outflow obstruction). After entering the stomach, the clinician retroflexes the tip of the endoscope and examines the lower esophageal sphincter for leiomyomas. Gastroduodenoscopy is performed concurrently to look for gastric and duodenal reasons for gastroesophageal reflux or vomiting. If fluoroscopy is available, the lower esophageal sphincter should be observed for several minutes to detect the frequency and severity of gastroesophageal reflux (normal animals may show occasional reflux).

#### **VOMITING**

Vomiting is usually caused by (1) motion sickness, (2) ingestion of emetogenic substances (e.g., drugs), (3) gastrointes-

Behavior

tinal (GI) tract obstruction, (4) abdominal (especially alimentary tract) inflammation or irritation, and (5) extragastrointestinal tract diseases that may stimulate the medullary vomiting center or the chemoreceptor trigger zone (Box 28-6). Occasionally, central nervous system (CNS) disease, behavior, and learned reactions to specific stimuli may cause vomiting. If the cause of the vomiting is not apparent on the basis of the history and physical examination findings, the next step depends on whether the vomiting is acute or chronic and whether there is hematemesis (Figs. 28-2 and 28-3). Remember that blood in vomitus may be fresh

(i.e., red) or partially digested (i.e., "coffee grounds" or "dregs").

In animals with acute vomiting without hematemesis, the clinician should first search for obvious causes (e.g., ingestion of a foreign body, intoxication, organ failure, parvovirus) as well as for secondary fluid, electrolyte, or acid-base abnormalities or sepsis that require prompt, specific therapy. If the animal's condition seems stable and there is no obvious cause, symptomatic treatment is often used for 1 to 3 days. If the animal is too sick for the clinician to take a chance on guessing wrong, if the vomiting persists for 2 to 4 days after

<sup>\*</sup>It is necessary to determine whether this is the cause of vomiting or an effect of vomiting.

**FIG 28-2**General diagnostic approach to vomiting in the dog and cat. *CBC*, Complete blood count; *FeLV*, feline leukemia virus; *FIV*, feline immunodeficiency virus; *CSF*, cerebrospinal fluid; *EEG*, electroencephalogram; *MRI*, magnetic resonance imaging.

the start of symptomatic therapy, or if the condition worsens during this initial time, then more aggressive diagnostic testing is usually indicated.

The clinician should search for historical evidence of the ingestion of foreign objects, toxins, inappropriate food, or drugs. Physical examination is used to look for abdominal abnormalities (e.g., masses), linear foreign objects caught under the tongue, and evidence of extraabdominal disease (e.g., uremia, hyperthyroidism). The clinician should always consider the possibility of linear foreign bodies in vomiting cats and carefully examine the base of the tongue. Chemical restraint (e.g., ketamine HCl, 2.2 mg/kg of body weight given intravenously) may be necessary to examine this area properly. The abdomen is palpated to search for masses or pain, but even careful palpation may miss short ileocolic intussusceptions in the craniodorsal area of the abdomen. It is reasonable to perform fecal examination for parasites because they can be the cause of vomiting. If a cause cannot be found and the animal is not unduly ill, the clinician may prescribe a therapeutic trial (e.g., pyrantel and a dietary trial; see Table 30-7 and Chapter 30). Therapeutic trials should be designed so that the failure of a treatment allows the clinician to exclude at least one disease and then look for others.

If acute vomiting does not respond to symptomatic therapy or if the animal is so sick that the clinician cannot take a chance on symptomatic therapy being ineffective, aggressive diagnostic testing is indicated. Animals with acute or chronic vomiting without hematemesis should undergo abdominal imaging (i.e., radiography, ultrasonography) to look for problems such as an intestinal obstruction, foreign objects, masses, pancreatitis, peritonitis, poor serosal contrast in the region of the pancreas, free abdominal fluid, or free abdominal gas. Abdominal ultrasonography can be more revealing than plain radiographs; however, radiographs may be more sensitive in revealing some foreign bodies. A CBC, serum biochemistry profile, and urinalysis are also indicated. Cats should be tested for feline leukemia virus, feline immunodeficiency virus, and hyperthyroidism. It may be necessary to measure serum bile acid concentrations (or blood ammonia concentrations) or perform an ACTH-stimulation test (or at least resting serum cortisol concentrations) to identify hepatic or adrenal insufficiency that is not indicated by results of routine serum biochemistry profiles.

If results of the CBC, chemistry profile, urinalysis, and routine abdominal imaging are not diagnostic, the next step is usually either contrast-enhanced abdominal radiography or endoscopy plus biopsy. Endoscopy is usually more cost-effective than contrast-enhanced radiography in vomiting patients. During endoscopy the clinician should biopsy the stomach and duodenum, regardless of the gross mucosal appearance. In cats endoscopic biopsy of the ilcum and ascending colon may be required to reveal the cause of vomiting. If laparotomy is chosen over endoscopy, the entire abdomen should be examined and biopsy of the stomach, duodenum, jejunum, ileum, mesenteric lymph node, liver, and, in cats, the pancreas should be performed.

If the cause of vomiting is undiagnosed after biopsy, the basis for previously excluding the different diseases should be reviewed. Diseases may be inappropriately ruled out (or diagnosed) because the clinician does not understand the

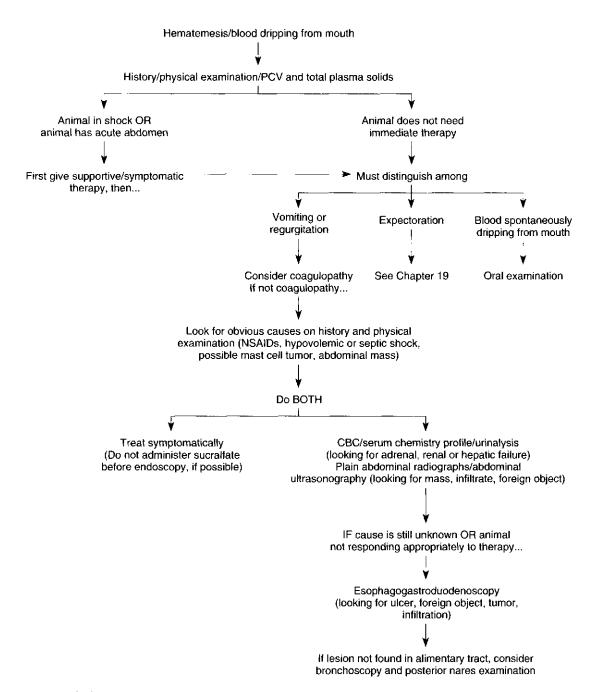

FIG 28-3
General diagnostic approach to hematemesis in the dog and cat. PCV, Packed cell volume; CBC, complete blood count.

limitations of certain tests. For example, dogs with hypoadrenocorticism may have normal electrolyte concentrations; inflammatory gastric and bowel disease may be localized to one area of the stomach or intestine and rarely causes significant changes in the white blood cell count; hyperthyroid cats may have normal serum thyroxine concentrations; dogs and cats with hepatic failure may have normal serum alanine aminotransferase and alkaline phosphatase activities; dogs and cats with pancreatitis may have normal serum amylase and lipase activities and normal abdominal ultrasound examinations; and *Physaloptera* infections are almost never diagnosed on the basis of fecal examination results. Finally, the clinician may have to consider less common diseases that are more difficult to diagnose (e.g., idiopathic gastric hypomotility, occult CNS disease, "limbic epilepsy").

#### HEMATEMESIS

The clinician must often use history and physical examination to help identify hematemesis as well as distinguish it from other problems. Hematemesis may involve expulsion of digested blood (i.e., "coffee grounds") or fresh blood. Animals with oral lesions that have blood dripping from their lips do not have hematemesis. Likewise, hemoptysis (i.e., coughing up blood) is not hematemesis.

The clinician should further distinguish vomiting that produces specks of blood from vomiting in which there is substantial blood present. The former may be caused by gastric mucosal trauma secondary to vigorous vomiting from any cause, and animals with such "hematemesis" should generally be treated as described in the previous section on vomiting. Patients that produce more substantial amounts of blood generally should be approached differently. Although hematemesis is usually caused by gastroduodenal ulceration and erosion (GUE), the clinician should not automatically start treating affected patients with antacids, cytoprotective agents, or sucralfate. Shock (e.g., hypovolemic, septic) and acute abdominal conditions should be eliminated first. The clinician should check the hematocrit and plasma total protein concentration to determine whether a blood transfusion is necessary (see Fig. 28-3). The clinician should next try to identify the cause, whether it is a coagulopathy (uncommon), the ingestion of blood from another site (e.g., the

respiratory tract), or GUE (Box 28-7). Historical and physical examination findings may help in ruling out a coagulopathy or respiratory tract disease as the cause. However, platelet counts and the clotting capability (e.g., one-stage prothrombin time, partial thromboplastin time, buccal mucosal bleeding time) are preferred. The clinician should then look for obvious causes of GUE (e.g., acute gastritis, hemorrhagic gastroenteritis [HGE], ulcerogenic drugs [e.g., nonsteroidal antiinflammatory drugs, dexamethasone], recent severe hypovolemic shock, systemic inflammatory response syndrome, abdominal masses that may involve the gastric mucosa, cutaneous mast cell tumors). It is important to remember that a mast cell tumor can grossly mimic almost any other benign or malignant neoplasm, especially lipomas.

If acute gastritis, HGE, nonsteroidal antiinflammatory drug-induced GUE, or GUE resulting from shock is strongly suspected, the clinician may elect a limited diagnostic workup (e.g., CBC, serum biochemistry panel) to define the degree of blood loss and look for evidence of renal or hepatic or adrenal failure. Then the animal can be treated symptomatically for 3 to 5 days (see pp. 407–409) to see what effect this has in controlling clinical signs. Endoscopy is not neces-

#### Coagulopathy (Uncommon)

Bleeding oral lesion

Gallbladder disease (rare)

#### Extraalimentary Tract Lesion (rare)

Respiratory tract disorders

Lung lobe torsion

Pulmonary tumor

Posterior nares lesion

<sup>\*</sup>Hematemesis caused by vigorous vomiting usually consists of specks of blood as opposed to larger quantities

sarily helpful in many of these cases because it cannot reliably distinguish between ulcers that will heal with medical therapy and those that will require surgical resection. However, if the cause is unknown and especially if the vomiting or blood loss is severe or chronic, more aggressive diagnostic tests (e.g., abdominal imaging, gastroduodenoscopy) should be done (see Fig. 28-3). The stomach and duodenum should be imaged, preferably by abdominal ultrasonography with or without plain radiographs to look for alimentary tract infiltrations, foreign objects, and masses. Endoscopy is the most sensitive and specific means of finding and evaluating gastroduodenal ulcers and erosions. The principal indications for endoscopy in animals with upper GI blood loss include (a) distinguishing potentially resectable ulcers from widespread, unresectable erosions in patients with lifethreatening GI bleeding; (b) localizing ulcers when considering surgical resection; and (c) determining the cause of GUE in patients with upper GI blood loss of unknown cause. During endoscopy the clinician should generally biopsy mucosa in an effort to rule out neoplasia or inflammatory bowel disease. Abdominal exploratory surgery may be performed instead of endoscopy, but it is easy to miss bleeding mucosal lesions when examining the serosal surface; intraoperative endoscopy (i.e., endoscopic examination of the mucosal surface of the stomach and duodenum while the abdomen is opened) may be useful in finding lesions that the surgeon cannot discern from the serosal surface.

If the source of bleeding cannot be found using gastroduodenoscopy, the clinician should consider possible bleeding sites beyond the reach of the endoscope; blood being swallowed from a lesion in the mouth, posterior nares, trachea, or lungs; hemorrhage from the gallbladder; or an intermittently bleeding gastric or duodenal lesion. Endoscopy of the trachea and choana can be diagnostic in some cases.

#### DIARRHEA

Diarrhea is excessive fecal water. Fecal mucus is principally caused by large bowel disorders and is discussed in the section on chronic large bowel diarrhea. The best approach to the assessment of animals with diarrhea is to first distinguish acute from chronic problems.

Acute diarrhea is usually caused by diet, parasites, or infectious diseases (Box 28-8). Dietary problems are often detected by history; parasites by fecal examination; and infectious diseases by history (i.e., evidence of contagion or exposure), CBC, fecal enzyme-linked immunosorbent assay for canine parvoviral antigen, and the exclusion of other causes. If acute diarrhea becomes unduly severe or persistent, additional diagnostic tests are recommended. The diagnostic approach for such a patient is similar to that adopted for the assessment of animals with chronic diarrhea.

Animals with chronic diarrhea should first be examined for evidence of parasites; multiple fecal examinations looking for nematodes, *Giardia*, and *Tritrichomonas* are indicated. Next, the clinician should determine whether the diarrhea

#### Differentiation of Chronic Small Intestinal from Large Intestinal Diarrheas

SIGN	SMALL INTESTINAL DIARRHEA	LARGE INTESTINAL DIARRHEA	
Weight loss*	Expected	Rare*	
Polyphagia	Sometimes	Rare to absent	
Frequency of bowel movements	Often near normal	Sometimes very increased	
Volume of feces	Often increased	Sometimes decreased (because of the increased frequency)	
Blood in feces	Melena (rare)	Hematochezia (sometimes†)	
Mucus in feces	Uncommon	Sometimes	
Tenesmus	Uncommon (but may occur later in chronic cases)	Sometimes	
Vomiting	May be seen	May be seen	

<sup>\*</sup>Failure to lose weight or condition is the most reliable indication that an animal has large bowel disease. However, animals with colonic histoplasmosis, pythiosis, lymphoma, or similar infiltrative diseases may have weight loss despite large bowel involvement. †Hematochezia becomes much more important as a differentiating feature in animals that are losing weight. Its presence in such animals confirms the presence of large bowel involvement (either by itself or in combination with small bowel disease) despite weight loss.

originates from the small or large intestine. History is the best tool (Table 28-2). Failure to lose weight or body condition despite chronic diarrhea almost always indicates large bowel disease. Weight loss usually indicates the presence of small bowel disease, although severe large bowel diseases (e.g., pythiosis, histoplasmosis, malignancy) may cause weight loss. Animals with weight loss resulting from severe large bowel disease usually have obvious signs of colonic involvement (i.e., fecal mucus, marked tenesmus, hematochezia). If there is tenesmus, the clinician must ascertain whether it was present when the disease began; if tenesmus did not begin until late in the course, it may be due simply to perineal scalding or anal soreness resulting from chronic irritation.

Chronic small intestinal diarrhea can be categorized as maldigestion, nonprotein-losing malabsorptive disease, and protein-losing malabsorptive disease. Maldigestion is principally caused by exocrine pancreatic insufficiency (EPI) and rarely causes significant hypoalbuminemia (i.e., serum albumin concentration of 2.0 g/dl or less if the normal range is 2.5 to 4.4 g/dl). Film digestion tests for fecal trypsin activity, Sudan staining of feces for undigested fats, and fat absorption tests yield many false-negative and false-positive results. The most sensitive and specific test for EPI is measuring the serum trypsin-like immunoreactivity (TLI; see p. 388), which is indicated in dogs with chronic small intestinal diarrhea. The cPLI test may have use in diagnosing EPI, but this is not yet certain. EPI is rare in cats, but if suspected, an fTLI (feline TLI) is recommended.

Diagnosing EPI by treating the animal and evaluating its response to therapy is not recommended. If the animal has apparently responded to pancreatic enzyme supplementation, the enzymes should be repeatedly withheld and then readministered to ensure that the enzymes are responsible for resolution of the diarrhea. A false-positive diagnosis of EPI results in the unnecessary supplementation of expensive enzymes. Second, up to 15% of dogs with EPI do not respond

when enzymes are added to their diet. If EPI is incorrectly ruled out in such a case, then unnecessary endoscopies or operations often result. Antibiotic-responsive enteropathy (ARE) may be responsible for causing such a failure to respond to proper enzyme supplements and dietary changes. Therefore the clinician should definitively diagnose or rule out EPI before proceeding with other diagnostic tests or treatments.

Malabsorptive intestinal disease may be protein-losing (PLE) or nonprotein-losing (Fig. 28-4). The serum albumin concentration will usually be markedly decreased (i.e., 2.0 g/dl or less; normal, 2.5 to 4.4 g/dl) in the former but not in the latter; hypoglobulinemia may develop in patients with PLE. Diarrhea occurs only if the absorptive capacity of the colon is exceeded. Therefore a dog or cat can be losing weight because of small intestinal malabsorption and not have diarrhea (see the section on weight loss). If an animal has marked hypoproteinemia not resulting from protein-losing nephropathy, hepatic insufficiency, or skin lesions, then PLE must be the main consideration.

In patients with nonprotein-losing malabsorptive disease, the clinician may perform additional diagnostic tests (e.g., intestinal biopsy) or design therapeutic trials depending on how ill the patient is. Therapeutic trials are the best way to diagnose antibiotic responsive enteropathy (ARE) or dietary responsive disease. ARE cannot reliably be diagnosed on the basis of quantitated duodenal culture, and decreased serum cobalamin plus increased serum folate concentrations are of dubious sensitivity. However, if a therapeutic trial is performed, the clinician must be sure that it is done properly (e.g., long enough, correct dose) so that it will almost certainly succeed if the animal has the suspected disease. If the patient seems particularly ill (e.g., substantial weight loss) or if PLE is suspected, ultrasonography and intestinal biopsy are often the preferred next steps because spending 2 to 3 weeks waiting to see if a therapeutic trial will work can be disasterous if the therapy is incorrect and the disease pro-

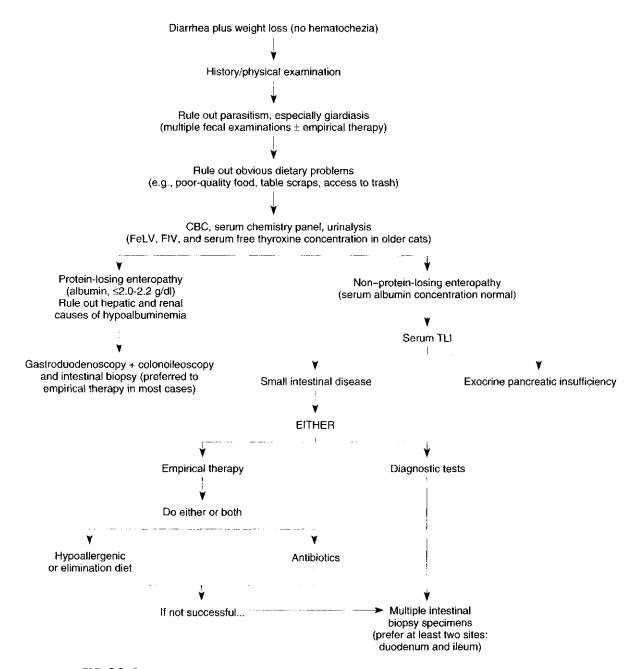

FIG 28-4
General diagnostic approach to small intestinal diarrhea in the dog and cat. CBC,
Complete blood count; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus, TLI,
trypsin-like immunoreactivity.

gresses. If diagnostic tests are chosen, abdominal imaging (especially ultrasonography) followed by gastroduodenoscopy or colonoscopy are typical next steps because the findings can help determine the cause of PLE and nonprotein-losing enteropathies in patients that do not have ARE or dietary responsive disease (Boxes 28-9 and 28-10). Absorptive tests and barium contrast—enhanced radiographs are rarely helpful. Abdominal ultrasonography may be diagnostic if it shows lymphadenopathy or intestinal infiltrates that can be aspirated percutaneously. Laparotomy or endoscopy can be performed to obtain biopsy specimens. If ultrasonog-

raphy reveals a localized lesion that cannot be reached with an endoscope, then laparotomy is necessary as opposed to endoscopy. Otherwise, endoscopy is quicker and safer than laparotomy and may allow the clinician to biopsy lesions not seen from the serosal surface. Endoscopic biopsy specimens can be nondiagnostic if the endoscopist has not been carefully trained in taking biopsy specimens. If laparotomy is performed in hypoalbuminemic animals, it may be prudent to use nonabsorbable suture material and/or perform intestinal scrosal patch grafting. The presence of distended intestinal lymphatics or lipogranulomas is suggestive of

lymphangiectasia. If a cause is not shown by intestinal biopsy specimens, the main possible reasons for this are that the specimens were inadequate (e.g., not deep enough, from the wrong place, too much artifact), the animal has occult giardiasis, the animal has ARE, the animal has a dietary intolerance, or there is localized lymphangiectasia or inflammation at a site other than the one biopsied.

Dogs with chronic large intestinal diarrhea (Box 28-11) should first undergo a digital rectal examination to search

BOX 28-9

#### Major Causes of Malabsorptive Disease

#### Dog

Dietary responsive (food intolerance or allergy; common and important)

Parasitism: giardiasis, nematodes (common and important) Antibiotic-responsive enteropathy (common and important) Inflammatory bowel disease

Neoplastic bowel disease (especially lymphoma; important but not common)

Fungal infections (regionally important)

Pythiosis

Histoplasmosis

#### Cat

Dietary responsive (food intolerance or allergy; common and important)

Parasitism: giardiasis

Inflammatory bowel disease: lymphocytic-plasmacytic enteritis (common and important)

Neoplastic bowel disease (especially lymphoma; common and important)

for mucosal thickening or proliferation. The rectum is the most common site of canine colonic neoplasia, and finding obvious mucosal lesions indicates the need for biopsy. If the rectal mucosa seems normal and the animal has not lost weight or become hypoalbuminemic (i.e., albumin <2.0 g/dl), it is often most appropriate to first try therapeutic trials.

BOX 28-10

#### Major Causes of Protein-Losing Enteropathy\*

#### Dog

Intestinal lymphangiectasia (common and important) Alimentary tract lymphoma (common and important) Severe inflammatory bowel disease

Alimentary tract fungal infections

Histoplasmosis (regionally important) Pythiosis

Chronic intussusception (especially young dogs)

Alimentary tract hemorrhage (e.g., ulceration or erosion, neoplasia, parasites)

Unusual enteropathies (e.g., chronic purulent enteropathy, severe ectasia of mucosal crypts)

Massive hookworm or whipworm infestation (regionally important)

#### Cat

Alimentary tract lymphoma
Severe inflammatory bowel disease
Alimentary hemorrhage (e.g., neoplasia, duodenal polyps, idiopathic ulceration)

\*Any gastrointestinal disease can cause protein-losing enteropathy, but these are the most common causes. Except for lymphangiectasia, these diseases do not consistently produce protein-losing enteropathy.

BOX 28-11

#### Major Causes of Chronic Large Intestinal Diarrhea

#### Dog

Dietary responsive (intolerance or allergy; important and common)

Fiber-responsive (important and common)

Functional disorder (so-called "irritable bowel syndrome")
Parasitism

Whipworms (regionally important and common)

Giardia (regionally important and common—small bowel disease that sometimes mimics large bowel disease)

Heterobilharzia (regionally important)

Bacterial diseases

"Clostridial" colitis (important and common)

Histiocytic ulcerative colitis (principally Boxers and French Bulldogs)

Fungal infections (regionally important and common)

Histoplasmosis

Pythiosis

Inflammatory bowel disease Neoplasia

Lymphoma

Adenocarcinoma

#### Ca

Dietary responsive (intolerance or allergy; important and common)

Fiber-responsive (important and common)

Functional disorder (so-called irritable bowel syndrome) Inflammatory bowel disease

Tritrichomonas

Feline leukemia virus infection (including infections secondary to it)

Feline immunodeficiency virus infection (specifically infections secondary to it)

However, multiple fecal examinations to detect whipworms, *Giardia* (a small bowel problem that can mimic large bowel disease), and *Tritrichomonas* are appropriate. Therapeutic trials usually consist of high-fiber diets, hypoallergenic diets, antibiotics to control "clostridial" colitis, or treatment for whipworms.

Additional diagnostic tests that may be done instead of therapeutic trials principally include obtaining biopsy specimens of the colonic mucosa by colonoscopy, fecal cultures, assays for clostridial toxin, and antigen tests for specific organisms (e.g., Campylobacter). Fecal cultures for specific pathogens (e.g., Salmonella spp.) should be done if the history indicates the possiblity of a contagious disorder or if the animal is not responding to seemingly appropriate therapy. Fecal cultures should be done before the animal receives enemas or intestinal lavagae solutions. Unless there is some epidemiologic reason to suspect an infectious bacteria, fecal cultures tend to be low-yield procedures that are difficult to interpret.

If the results of these tests are not diagnostic, the clinician must consider three main possibilities. First, the biopsy specimens may not be representative of the entire colonic mucosa. For example, if the disease is localized to the region of the ileocolic valve, it will be necessary to use a flexible endoscope to reach the area. Second, the pathologist may not have recognized the lesions. This occasionally happens, especially if animals have colonic histoplasmosis or neoplasia. Third, there may be no mucosal lesions. This typically occurs in animals with a dietary intolerance or allergy, "clostridial" colitis, chronic giardiasis, or irritable bowel syndrome (i.e., fiber-responsive diarrhea), all common problems in dogs.

#### HEMATOCHEZIA

If the patient has hematochezia (fresh blood in the feces) and diarrhea, the problem should usually be approached in the same way as that for animals with large bowel diarrhea (see p. 362). The patient with normal stools plus hematochezia is approached slightly differently. Streaks of blood on the outside of otherwise normal feces usually indicates the presence of a distal colonic or rectal lesion, whereas blood that is mixed into the feces suggests that bleeding is occurring higher in the colon. Coagulopathies are rarely a cause of rectal bleeding only. Focal bleeding lesions in the distal colon, rectum, or perineal region (Box 28-12) are especially important. Acute hematochezia may also result from trauma.

A thorough digital rectal examination is the best initial step (even if anesthesia is necessary). The clinician should express each anal sac repeatedly and examine the contents. If the problem is chronic and results of these tests are uninformly negative, then colonoscopy and biopsy are usually indicated. An excellent barium enema is usually inferior to a good endoscopic examination. Biopsy specimens should include the submucosa, or some neoplastic lesions will be missed. Hematochezia is rarely severe enough to cause anemia; however, a CBC can be performed to look for and evaluate the cause of anemias.

#### MELENA

Melena is caused by digested blood and is seen as coal tar black (not dark) feces. The clinician must be extremely careful to distinguish melena from stools that are intensely

Coagulopathies: vitamin K deficiency (intoxication or result

ing from malabsorption)

dark green. Melena is strongly suggestive of upper alimentary tract bleeding or the ingestion of blood (Box 28-13). However, a lot of blood must enter the GI tract in a short time to produce melena, which is why most animals with upper GI hemorrhage do not have melena. A CBC is indicated to look for iron deficiency anemia (i.e., microcytosis, hypochromasia, thrombocytosis). Measuring the total serum iron concentration and the total iron-binding capacity plus staining the bone marrow for iron are more definitive tests for iron deficiency anemia. Ultrasonongraphy is very useful when looking for infiltrated, bleeding lesions (e.g., an intestinal tumor). Gastroduodenoscopy is the most sensitive test for GUE (which is often missed by ultrasonography). If gastroduodenoscopy is nonrevealing, then contrast-enhanced radiography may detect small intestinal lesions beyond the reach of the endoscope. If imaging reveals a lesion beyond the reach of the endoscope, exploratory laparotomy is required. The clinician may elect to perform exploratory surgery immediately, but it is easy to miss bleeding mucosal lesions when examining the serosa or palpating the bowel. Intraoperative endoscopy may be helpful if surgery is performed but no lesion is detected.

#### **TENESMUS**

Tenesmus (i.e., ineffectual or painful straining at urination or defecation) and dyschezia (i.e., painful or difficult elimi-

Constipation

Abscess near rectum

nation of feces from the rectum) are principally caused by obstructive or inflammatory distal colonic or urinary bladder or urethral lesions (Box 28-14). Colitis, constipation, perineal hernias, perianal fistulas, prostatic disease, and cystic/ urethral disease are the most common causes of tenesmus. Most rectal masses and strictures cause hematochezia; however, some do not disrupt the colonic mucosa and cause only tenesmus.

The first goal (especially in cats) is to distinguish lower urinary tract from alimentary tract disease. In cats tenesmus secondary to a urethral obstruction is often misinterpreted as constipation. By observing the animal, the clinician may be able to determine whether the animal is attempting to urinate or defecate. The clinician palpates the bladder (a distended urinary bladder indicates an obstruction; a small, painful bladder indicates inflammation); performs a urinalysis; and, if necessary, catheterizes the urethra to determine whether it is patent.

If the clinician suspects tenesmus resulting from alimentary tract disease, he or she should palpate the abdomen and rectum and visualize the anus and perineal areas. The clinician should not assume that constipation, if present, is causing the tenesmus. Severe pain (e.g., that resulting from proctitis) may make the animal refuse to defecate and cause secondary constipation. Most strictures, perineal hernias, masses, enlarged prostates, pelvic fractures, and rectal tumors can be detected during a digital rectal examination. The

<sup>\*</sup>These diseases do not consistently produce melena; however, if melena is present, these are the most common causes.

clinician may need to use two fingers to detect partial strictures when examining large dogs. Perianal fistulae are usually visible but may be detected only as perirectal thickenings. Next, the clinician expresses the anal sacs and examines their contents. Finally, the clinician evaluates the feces to determine whether they are excessively hard or have abnormal contents (e.g., hair, trash).

A biopsy should be done of any mass, stricture, or infiltrative lesion found by rectal examination. A rectal scraping is sometimes sufficient (e.g., histoplasmosis), but biopsy specimens that include the submucosa are usually preferred. Fine-needle aspiration should be performed on extracolonic masses because abscesses occasionally occur in extracolonic locations.

If the clinician is confused by the findings from a physical examination, observing the animal defecate may help define the underlying process. Animals with inflammation often continue to strain after defecating, whereas a constipated animal strains before feces are produced. Tenesmus that occurs when an animal is in a squatting position often results from colitis, whereas tenesmus that occurs when an animal is in a semiwalking or partial squatting position usually results from constipation.

#### CONSTIPATION

Constipation (the infrequent and difficult evacuation of feces) and obstipation (intractable constipation) have several causes (Box 28-15). The initial use of symptomatic therapy is often successful, but it is also important to look for causes because some problems may become harder to treat if symptomatic therapy masks the signs while the underlying disease progresses.

A search of the history for iatrogenic, dietary, environmental, or behavioral causes should be done. Feces should be examined to determine whether they contain plastic, bones, hair, popcorn, or other such material. Physical and rectal examinations are done to search for rectal obstruction or infiltration. Plain pelvic radiographs can help show whether the animal has anatomic abnormalities or a previously undetected colonic obstruction (e.g., prostatomegaly, enlarged sublumbar lymph node). Ultrasonography is the preferred technique when looking for infiltrates. A serum biochemistry panel may reveal causes of colonic inertia (e.g., hypercalcemia, hypokalemia, hypothyroidism).

Colonoscopy is indicated if the clinician suspects an obstruction too orad to be detected by digital examination.

Granuloma

**Abscess** 

Healed pelvic fracture

Prostatomegaly

Prostatic or paraprostatic cyst Sublumbar lymphadenopathy

#### Colonic Weakness

Systemic disease

Hypercalcemia

Hypokalemia

Hypothyroidism

Localized neuromuscular disease

Spinal cord trauma

Pelvic nerve damage

Dysautonomia

Chronic, massive dilation of the colon causing irreversible stretching of the colonic musculature

#### Miscellaneous Causes

Severe dehydration

Idiopathic megacolon (especially cats)

Ultrasound-guided fine-needle aspiration of infiltrative colonic lesions sometimes yields diagnostic findings, but colonoscopy (especially rigid) allows a more reliable biopsy specimen to be obtained. If a thorough diagnostic workup fails to identify a cause in a patient with a grossly dilated colon, idiopathic megacolon may be present.

#### FECAL INCONTINENCE

Fecal incontinence is caused by neuromuscular disease (e.g., cauda equine syndrome, lumbosacral stenosis) or a partial rectal obstruction. Severe irritative proctitis may cause urge incontinence. Animals with rectal obstructions continually try to defecate because the anal canal is filled with feces. Proctitis is suspected on the basis of rectal examination findings and confirmed by proctoscopy and biopsy findings. Neuromuscular disease is suspected if an abnormal anal reflex is found, usually in conjunction with other neurologic defects in the anal, perineal, hindlimb, or coccygeal region. Defects in the coccygeal region are discussed in Chapter 70.

#### **WEIGHT LOSS**

Weight loss is usually caused by one of several categories of problems (Box 28-16). If other problems with more defined lists of differentials (e.g., ascites, vomiting, diarrhea, polyuria/polydipsia) are also present, they should usually be investigated first because it may be easier to find the cause. If there are no such concurrent problems that allow relatively prompt localization of the disease, the clinician should then determine what the animal's appetite was when the weight loss began (Fig. 28-5). Almost any disease can cause anorexia. Weight loss despite a good appetite usually indicates maldigestion, malabsorption, or excessive utilization (e.g., hyperthyroidism, lactation) or inappropriate loss (e.g., diabetes mellitus) of calories.

The animal's history should be reviewed for evidence of dietary problems, dysphagia, regurgitation, vomiting, or increased use of calories (e.g., lactation, work, extremely cold temperature). Signalments suggestive of particular diseases (e.g., hyperthyroidism in older cats, hepatic failure in younger dogs with signs of portosystemic shunts) should be recognized. It is important to remember that diarrhea may be absent in animals with severe small intestinal disease.

Physical examination is performed to identify abnormalities that might help localize the problem to a particular body system (e.g., nasal disease preventing normal olfaction, dysphagia, arrhythmia suggestive of cardiac failure, weakness suggestive of neuromuscular disease, abnormally sized or shaped organs, abnormal fluid accumulations). Retinal examination may identify inflammatory or infiltrative diseases, especially in cats.

A CBC, serum biochemistry profile, and urinalysis should be done next to search for evidence of inflammation, organ

#### Causes of Weight Loss

#### Food

Not enough (especially if there are multiple animals)
Poor quality or low caloric density
Inedible

Anorexia (see Box 28-17)

Dysphagia (see Box 28-1)

**Regurgitation/Vomiting** (i.e., losing enough calories to account for weight loss; see Boxes 28-4 to 28-6)

#### Maldigestive Disease

Exocrine pancreatic insufficiency (usually but not always associated with diarrhea)

#### Malabsorptive Disease (see Box 28-9)

Small intestinal disease (may be associated with normal stools)

#### Malassimilation

Organ failure Cardiac failure Hepatic failure Renal failure Adrenal failure

#### Cancer Cachexia

#### Neuromuscular Disease

Lower motor neuron disease

failure, or a paraneoplastic syndrome. Cats should be tested for circulating feline leukemia virus antigen and antibodies to feline immunodeficiency virus. Serum  $T_4$  (and sometimes  $fT_4$ ) concentrations should be determined in middle-aged to older cats. If clinical pathology data are not helpful, imaging is usually the next step. Thoracic radiographs (ventrodorsal and both lateral views) are important because significant thoracic disease cannot be ruled out on the basis of physical examination findings alone. Most cats and some dogs can be palpated well enough that abdominal radiographs are not cost-effective early in the workup. However, abdominal ultrasonography may reveal focal or infiltrative lesions that

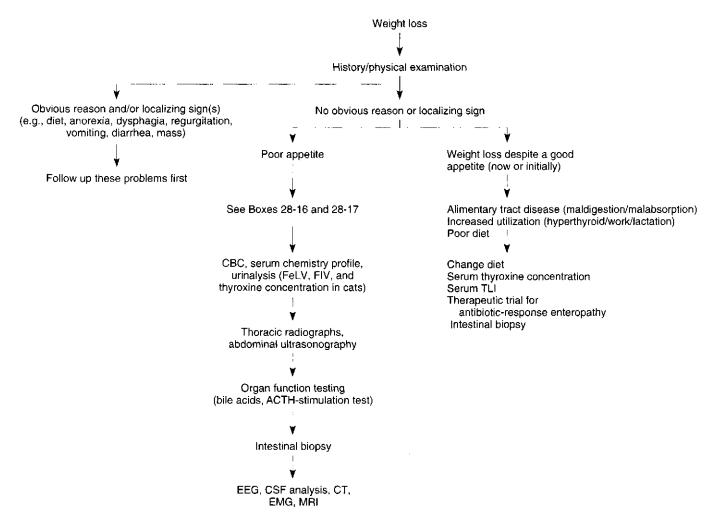

FIG 28-5

General diagnostic approach to weight loss in the dog and cat. CBC, Complete blood count; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; ACTH, adrenocorticotropic hormone; EEG, electroencephalography; EMG, electromyography; CT, computed tomography; CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

cannot be palpated (plain radiographs reveal such lesions less frequently).

If the cause of weight loss remains unknown after these steps have been taken, additional tests are necessary. Daily physical examinations can be an important means of localizing the problem. Fever of unknown origin may be noted (see Chapter 90). Organ function testing (e.g., serum bile acid concentrations, ACTH–stimulation testing, serum TLI, serum cobalamin) is reasonable. Likewise, if serum  $T_4$  concentrations are normal in a cat with suspected hyperthyroidism, the serum  $fT_4$  concentration should be determined or other tests (e.g., nuclear scintigraphy) performed (see Chapter 51).

If the cause of weight loss still remains undiagnosed, the clinician should consider performing gastric and intestinal biopsy (preferably endoscopically). If a laparotomy is performed instead, the entire abdomen should be examined, multiple biopsy samples of the alimentary tract obtained, and biopsy of the liver and mesenteric lymph nodes done. Biopsy of the pancreas should also be done in cats.

Other possible diagnostic tools include tests to evaluate the CNS (i.e., cerebrospinal fluid analysis, electroencephalography, computed tomography, magnetic resonance imaging; animals that are anorectic as a result of severe CNS disease do not always have obvious cranial nerve deficits or seizures) and peripheral nerves and muscles (i.e., electromyography, muscle or nerve biopsies; sometimes the weakness associated with neuropathies and myopathies is mistaken for lethargy). (See Chapter 64.) If the cause of the weight loss still remains undiagnosed and the history and physical examination findings are still noncontributory, occult cancer becomes a major differential diagnosis. In such cases, the clinician may have to wait and retest later with the hope that the disease will progress enough to be detected.

Causes of weight loss that can be particularly difficult to diagnose include gastric disease that does not cause vomiting, intestinal disease that does not cause vomiting or diarrhea, hepatic disease with normal serum alanine aminotransferase or alkaline phosphatase activities, occult inflammatory disease, hypoadrenocorticism with normal serum electrolyte concentrations, occult cancer, "dry" feline infectious peritonitis, and CNS disease without cranial nerve deficits or seizures.

#### **ANOREXIA**

The approach to the diagnostic evaluation of animals with anorexia of uncertain cause is similar to that for animals with weight loss (see Fig. 28-5), and the differential diagnoses are also similar (Box 28-17). Inflammatory disease is often detected by the CBC or the finding of fever (see Chapter 90). GI disease may produce anorexia without vomiting or diarrhea. Cancer cachexia (with anorexia as the predominant sign) may stem from relatively small tumors that are not grossly detectable, although this is rare. Finally, CNS disease must be considered whenever there is altered mentation. However, altered mentation may resemble the depression and lethargy commonly seen in animals with other diseases.

Dysphagia (especially resulting from pain)

Nausea (stimulation of the medullary vomiting center for any reason, even if it is not sufficient to cause vomiting, especially gastric or intestinal disease; see Box 28-6)

#### Metabolic Disease

Organ failure (e.g., kidney, adrenal, liver, heart)

Hypercalcemia

Diabetic ketoacidosis

Hyperthyroidism (usually causes polyphagia, but some cats have apathetic hyperthyroidism)

#### Central Nervous System Disease

Cancer Cachexia

Anosmia

**Psychologic Causes** 

#### **ABDOMINAL EFFUSION**

Abdominal effusion is usually caused by hypoalbuminemia, portal hypertension, or peritoneal inflammation. Effusions resulting from alimentary tract disorders are primarily caused by PLE or alimentary tract rupture (i.e., septic peritonitis). Some animals with PLE have normal stools, with ascites being the presenting complaint. Malignant tumors may obstruct lymphatic flow or increase vascular permeability, causing modified transudates to form or nonseptic peritonitis to develop. Modified transudates usually result from hepatic or cardiac disease or from malignant conditions. For further information on abdominal effusions, see Chapters 35 and 36.

#### **ACUTE ABDOMEN**

Acute abdomen refers to various abdominal disorders producing shock (hypovolemic or septic), sepsis, or severe pain (Box 28-18). Causes may include alimentary tract obstruction or leakage, vascular compromise (e.g., congestion, torsion, volvulus, ischemia), inflammation, neoplasia, or sepsis. The diagnostic evaluation of this problem is determined by the severity of the clinical signs (Fig. 28-6).

Shock and gastric dilation or volvulus (GDV) must be identified and treated immediately. Once these conditions are climinated, the next major decision is whether to perform exploratory surgery or initiate medical therapy. Animals with abdominal masses, foreign objects, bunched-up loops of painful small intestine (e.g., linear foreign body), or spontaneous septic peritonitis should typically undergo surgery as soon as supportive therapy has made the risk of anesthesia acceptable. If the cause of the acute abdomen is uncertain, it can be difficult to determine whether surgery is indicated. Surgery is not necessarily beneficial and may even be detrimental to animals with conditions such as pancreatitis, parvoviral enteritis, pyelonephritis, or prostatitis. Typically, abdominal imaging (i.e., plain abdominal radiography or ultrasonongraphy) and clinical pathologic studies (i.e., CBC, chemistry panel) should be performed before a laparotomy is performed. Ultrasound can reveal changes (e.g., infiltration) that radiographs cannot detect, sometimes allowing diagnosis via aspiration (and potentially eliminating the need for surgery). However, radiographs occasionally detect lesions (e.g., small foreign bodies) that were missed ultrasonographically. Imaging may reveal spontaneous pneumoperitoneum, abdominal masses, foreign objects, alimentary tract obstruction, gastric or mesenteric torsion (these require surgical treatment), or free peritoneal fluid (this requires abdominocentesis and fluid analysis for management). A barium series is seldom needed and may complicate later therapy/surgery.

If optimal medical therapy is being given and the animal's condition is clearly deteriorating or does not improve after 2 to 5 days of therapy, or if the animal continues to have excruciating pain, it is often appropriate to recommend exploratory surgery. Inform the client that you may discover

### Major Causes of Acute Abdomen

### Septic Inflammation

Septic peritonitis

Perforated gastric ulcer (NSAIDs, tumor) (important)
Perforated intestines (tumor, post-op dehiscence, linear foreign body, severe inflammation) (important and common)

Devitalized intestines (intussusception, thrombosis/infarct) Ruptured gallbladder due to septic cholecystitis or mucocoele

Abscess/Infection

the animal has a disorder not surgically correctable (especially pancreatitis) or that nothing abnormal may be found. In the latter case, the clinician should biopsy various abdominal organs and then treat the animal's symptoms while awaiting biopsy results.

### ABDOMINAL PAIN

"Abdominal" pain must first be determined to be abdominal and not extraabdominal in origin (e.g., thoracolumbar pain is often erroneously assessed as being abdominal in origin).

An animal with true abdominal pain may show obvious discomfort (e.g., it paces or repeatedly assumes different positions, repeatedly looks at or licks its abdomen) and may whine, growl, or snap if the abdomen is touched. Some dogs stretch out and assume a "praying" position (i.e., the "position of relief"). Other animals have inconspicuous signs (e.g., the animal grunts or tries to walk away when palpated, the abdomen is tensed) that are easily missed. On the other hand, a poor or rough abdominal palpation technique in normal animals may elicit a guarding response that can mimic abdominal pain. The main causes of abdominal pain are listed in Box 28-19.

### Causes of Abdominal Enlargement

#### Tissue

Pregnancy

Hepatomegaly (infiltrative or inflammatory disease, lipidosis, neoplasia)

Splenomegaly (infiltrative or inflammatory disease, neoplasia, hematoma)

Renomegaly (neoplasia, infiltrative disease, compensatory hypertrophy)

Miscellaneous neoplasia Granuloma (e.g., pythiosis)

#### Fluid

Contained in organ(s)

Congestion resulting from torsion, volvulus, or right-sided heart failure

Spleen Liver

Cysts

Paraprostatic cyst

Perinephric cyst Hepatic cyst

Hydronephrosis

Intestines or stomach (resulting from obstruction or ileus)

Pyometra

Free in abdomen

Transudate, modified transudate, exudate, blood, chyle

#### Gas

Contained in organ(s)

Stomach (gastric dilation or volvulus)

Intestines (resulting from obstruction)

In parenchymatous organs (e.g., liver) resulting from infection with gas-producing bacteria

Free in abdomen

latragenic (after laparoscopy or laparotomy)
Alimentary tract or female reproductive tract rupture

Bacterial metabolism (peritonitis)

### Fat

Obesity Lipoma

### Weak Abdominal Muscles

Hyperadrenocorticism

Faces

If the patient has abdominal pain, the goal is to determine the source. If the pain is originating from within the abdominal cavity, the diagnostic approach depends on its severity, the progression of disease, and whether there are any obvious causes. The steps taken in diagnosing the cause of abdominal pain are similar to those taken in an animal with acute abdomen. Some causes of abdominal pain can be difficult to diagnose (e.g., acute pancreatitis, localized peritonitis).

# ABDOMINAL DISTENTION OR ENLARGEMENT

Abdominal distention or enlargement may be associated with an acute abdomen, but these conditions are typically separate problems. It is best to believe clients who claim there is abdominal enlargement until good cause is found to do otherwise. There are six main causes of abdominal distention (Box 28-20).

The first concern is whether an acute abdomen is present (e.g., GDV, septic peritonitis, hemoabdomen plus shock). After an acute abdomen is ruled out, it should be possible to classify the enlargement on the basis of the physical examination and abdominal imaging (i.e., radiography or ultrasonography) findings, according to the criteria in Box 28-20. Obesity and pregnancy should be obvious. Specimens of free abdominal fluid should be obtained and analyzed as described in Chapter 36. Biopsy should be performed

on abdominal masses and enlarged organs, unless there is a reason not to (e.g., hepatomegaly caused by severe rightsided heart failure). Fine-needle aspiration is usually safe, although the leakage of septic contents or implantation of neoplastic cells may occur. Ultrasonography helps determine the potential for hemorrhage or leakage (e.g., cyst, mass with ultrasonographic characteristics of hemangiosarcoma). The finding of a spontaneous pneumoperitoneum suggests alimentary tract rupture or septic peritonitis and is an indication for immediate surgical exploration. A hollow viscus dilated with gas may indicate obstruction (i.e., gastric dilation, intestinal obstruction) or physiologic ileus (see pp. 384 and 436; Figs. 29-5 and 32-4). Surgery is indicated if an obstruction seems likely. If abdominal musculature weakness is suspected, the clinician should test for hyperadrenocorticism. Results of a CBC, serum biochemistry panel, and urinalysis are used to look for specific organ involvement (e.g., hyperadrenocorticism). Contrast-enhanced alimentary or urinary tract radiographs may be useful in selected cases, although ultrasonography often makes such techniques unnecessary.

# PHYSICAL EXAMINATION

Routine physical examination is the first step in evaluating animals with alimentary tract disease, although oral examination is sometimes skipped in uncooperative animals. If oral, abdominal, or rectal disease is a major concern and the patient refuses to allow examination of the area, it is reasonable and appropriate to sedate or anesthetize the patient to examine and palpate this area. A common example of this is a vomiting cat with a possible linear foreign body lodged under the tongue; the clinician must thoroughly examine the mouth, even if it requires chemical restraint.

The clinician should methodically identify individual organs during abdominal palpation. In dogs the small intestine, large intestine, and urinary bladder can usually be found (unless there is an abdominal effusion, abdominal pain, or obesity). In cats both kidneys are usually palpable. In both species the clinician can usually detect substantial splenomegaly, hepatomegaly, intestinal or mesenteric masses, and intestinal foreign objects. Abdominal pain may be subtle; some animals will cry out during gentle palpation, whereas many just tense their abdomen (i.e., guarding) or try to move away. A rough palpation technique can cause a normal animal to tense up or vocalize during palpation, mimicking the reaction of an animal with abdominal pain. Light, careful palpation permits the definition of as much of the internal abdominal contents as possible. If sufficient abdominal fluid is present to prevent meaningful abdominal palpation, ballottement of the abdomen should produce a fluid wave.

During a rectal examination, the examiner should be able to identify and evaluate the colonic mucosa, anal sphincter, anal sacs, pelvic canal bones, muscular support for the rectum, urogenital tract, and luminal contents. However, it is particularly easy to misinterpret mucosal polyps as mucosal folds and to miss partial strictures that are large enough to allow a single digit to pass through easily.

# **ROUTINE LABORATORY EVALUATION**

### **COMPLETE BLOOD COUNT**

Complete blood counts (CBCs) are especially important in animals at risk for neutropenia (e.g., parvoviral enteritis, severe sepsis), infection (e.g., aspiration pneumonia), or anemia (e.g., pale mucous membranes, melena, hematemesis) and also in those that have fever, weight loss, or anorexia resulting from an occult cause. The clinician should always evaluate absolute numbers of the different types of white blood cells (WBCs), not the percentages, because an animal may have an abnormal percentage of a particular WBC and yet have a normal absolute number of cells (and vice versa). If the animal is anemic, the clinician should evaluate the CBC for evidence of iron deficiency (e.g., hypochromasia, microcytosis, thrombocytosis, increased red blood cell distribution width).

### COAGULATION

A platelet count is important. Platelet numbers can be estimated on the basis of correctly made blood smears (i.e., a dog should have an average of 8 to 30 platelets per oil immersion field; finding 1 platelet per field suggests a platelet count of approximately 15,000 to 20,000/µl). Coagulation panels may detect unsuspected coagulopathies (e.g., disseminated intravascular coagulation). Activated clotting times are crude estimates of the intrinsic clotting pathway; partial thromboplastin times are more sensitive. Mucosal bleeding time is an excellent screening test for coagulopathies severe enough to cause clinical bleeding.

### SERUM BIOCHEMISTRY PROFILE

Serum biochemistry profiles that include alanine transaminase and alkaline phosphatase activities, as well as the blood urea nitrogen, creatinine, total protein, albumin, sodium, potassium, chloride, total CO<sub>2</sub>, cholesterol, calcium, phosphorus, magnesium, bilirubin, and glucose concentrations, are important in animals with severe vomiting, diarrhea, ascites, unexplained weight loss, or anorexia. These values are crucial to correctly diagnosing the animal's problem and appropriately treating it. The clinician cannot predict the changes that will occur or the magnitude of the changes in a particular animal, even when the cause of the disease is known. The total carbon dioxide concentration is not as definitive as blood gas analysis but helps define the acid-base status, which also cannot be accurately predicted.

The albumin concentration is more useful than the total protein concentration. Hyperglobulinemia, which has many causes (e.g., heartworms, chronic dermatitis, ehrlichiosis) in a hypoalbuminemic dog can cause the serum total protein concentration to be normal. Severe hypoalbuminemia (i.e., less than 2.0 g/dl) is important diagnostically; it is more commonly found in animals with infiltrative alimentary tract disease, parvoviral diarrhea, intestinal lymphangiectasia, gastrointestinal blood loss, or ascites. It is important to have the serum albumin measured by technology designed for canine and feline albumin; some techniques used for

measuring human albumin result in falsely low measurements of canine albumin.

Ill animals (especially those receiving multiple drugs) are at risk for secondary renal or hepatic failure. Very young and very small animals easily become hypoglycemic if they cannot eat or absorb ingested nutrients. Finally, finding hypercalcemia or hypoalbuminemia may provide a clue to the underlying problem (i.e., make some disorders more likely) in animals with weight loss or anorexia.

### **URINALYSIS**

Urinalysis is required to accurately evaluate renal function and, in conjunction with the urine protein:creatinine ratio, to help identify the cause of hypoalbuminemia. Urine should always be obtained before fluid therapy is begun.

### FECAL PARASITIC EVALUATION

Fecal flotation is indicated in almost every animal with alimentary tract disease or weight loss, especially in puppies and kittens. Even if it is not the primary problem, parasitism may cause additional debilitation. Concentrated salt or sugar solutions are typically used for fecal flotation. The former are usually superior, although incorrectly made solutions may not force heavier ova (e.g., whipworms) to float. Moreover, concentrated salt solutions can distort Giardia cysts, making identification difficult. A zinc sulfate flotation solution is preferred for detecting nematode ova and Giardia cysts. Centrifugation is strongly recommended; it promotes separation of cysts from the fecal matter and results in a more sensitive fecal examination. Some parasites intermittently shed small numbers of ova or cysts, necessitating repeated fecal analyses for diagnosis. Whipworm and Giardia infections can be especially difficult to diagnose.

The ova of the most common tapeworm species are contained in segments and are not found by flotation techniques. Nanophyetus salmincola (the fluke that transmits salmon poisoning) is detected by many flotation solutions, although sedimentation examinations are required to detect most other fluke ova. Cryptosporidiosis can be detected by flotation techniques, but higher magnification (×1000) must be used. The clinician should send the feces to a laboratory that is familiar with this coccidium and is able to perform special procedures to detect it. ELISA methodology is more sensitive than fecal examination for finding cryptosporidia.

Direct fecal examination, although convenient, is not sensitive for nematodes and should not replace flotation techniques. However, occasionally amebiasis, strongyloidiasis, and whipworm infections missed by flotation procedures can be detected in this way. Motile *Giardia* and *Tritrichomonas* trophozoites may be found if the feces are very fresh and the smear is adequately diluted with saline solution. Direct examination seems about half as sensitive as zinc sulfate flotation techniques in detecting giardiasis.

Fecal sedimentation is time-consuming and offers no advantage in detecting common gastrointestinal tract parasites. However, it does detect fluke ova missed by other techniques, especially the ova of Eurytrema spp., Platynosomum spp., and Amphimerus spp. plus Heterobilharzia.

Feces may be preserved by mixing equal volumes of feces and 10% neutral buffered formalin or by using commercially available kits. Polyvinyl alcohol is used in the latter, and feces preserved in this manner can be examined weeks to months later. These techniques are especially useful if one cannot immediately examine feces for protozoal cysts.

### **FECAL DIGESTION TESTS**

Examining feces for undigested food particles by staining thin fecal smears with the Sudan stain (for fat) or iodine (for starch and muscle fibers) is of dubious value. Although the finding of excessive amounts of undigested fecal fat is suggestive of exocrine pancreatic insufficiency (EPI), this test has many false-positive and false-negative results. If EPI is a differential diagnosis, serum trypsin-like immunoreactivity (TLI) is a better way to confirm the diagnosis (see the section on digestion and absorption tests).

Fecal analysis for proteolytic activity (i.e., the fecal trypsin content) also tests for EPI. Qualitative estimates (e.g., fecal film digestion, fecal gelatin digestion) are unreliable. Quantitative analysis is seldom needed because the TLI test is easier and more pleasant to perform. It is rarely necessary to quantitate fecal proteolytic activity to diagnose EPI caused by pancreatic duct obstruction, something TLI does not detect. In this test feces are collected for 3 consecutive days and stored frozen until sent to the laboratory. However, this is an exceedingly rare situation.

Quantitated fecal fat analysis is seldom indicated. Although sensitive for detecting fat malabsorption and maldigestion, it is expensive and unpleasant to perform and does not differentiate malabsorption from EPI.

Fecal occult blood analyses are seldom useful because most pets eat meat by-products that cause a positive reaction. False-positive reactions may also be produced by cimetidine, oral iron preparations, and some vegetables. Furthermore, the sensitivity of different techniques varies, making it difficult to accurately compare results. Finally, blood is often not distributed homogeneously throughout the feces, and a negative result could stem from a sampling error (especially in animals with lower intestinal tract problems).

If analysis for fecal occult blood is desired, the optimal approach is to feed the animal a meat-free diet for 3 to 4 days before performing the test. Tests using the reagents benzidine or orthotoluidine to detect hemoglobin tend to be very sensitive (and hence less specific), whereas those using guaiac are less sensitive (and thus more specific). A sensitive and specific fluorometric method has been validated in dogs. Repeated testing may be necessary to demonstrate intermittent bleeding.

### MISCELLANEOUS FECAL ANALYSES

Enzyme-linked immunosorbent assays (ELISAs) can be used to detect various antibodies or antigens. The test for canine parvovirus seems to be very specific. However, virus may not be found in the feces for the first 24 to 48 hours, and it may be necessary to repeat the test in 2 to 3 days if initial results are negative in a dog strongly suspected of having parvoviral infection. In addition, although dogs with parvoviral diarrhea initially shed large amounts of virus, fecal shedding decreases substantially during the ensuing 7 to 14 days. A repeatedly negative test result therefore does not rule out parvoviral infection, but it does necessitate a consideration of other acute, febrile gastroenteritides (e.g., salmonellosis). This test is particularly valuable if there are epidemiologic considerations (e.g., breeding kennel).

ELISAs for detecting a *Giardia*-specific antigen in human (ProSpecT/Microplate ELISA assay for Giardia, Alexon, Inc.) and canine/feline feecs (SNAP Giardia Test, Idexx Laboratories) are available. The SNAP *Giardia* test appears to be sensitive and specific but has not been carefully compared with multiple zinc sulfate flotation examinations in clinical patients. It has the advantage of being able to be performed in the practice. An IFA test (MERIFLUOR *Cryptosporidium/Giardia* direct immunofluorescent kit, Meridian Bioscience, Inc.) appears to be specific but has the disadvantage of requiring that feecs be sent to a commercial laboratory.

ELISAs for detecting cryptosporidial antigens in feces (ProSpecT Cryptosporidium Microplate Assay, Meridian Diagnostics, Inc. and ProSpecT Cryptosporidium microplate assay, Remel Inc.) appear to be more sensitive than routine fecal examinations. Special staining of fecal smears with a modified Ziehl-Neelsen acid-fast technique is also sensitive, albeit more labor intensive. An IFA test (MERI-FLUOR Cryptosporidium/Giardia direct immunofluorescent kit, Meridian Bioscience, Inc.) was not as sensitive as the ELISAs when looking for cryptosporidia.

Electron microscopy can be used to identify various viral particles (e.g., coronavirus, astrovirus) in feces. Because the ELISA is usually adequate for detecting parvovirus, electron microscopy is rarely necessary. However, it is reasonable to choose this technique if other test results are not diagnostic and there are epidemiologic considerations. Fecal samples for electron microscopy analysis should be obtained early in the disease because fecal viral concentrations may decrease dramatically within 7 to 14 days after the onset of signs. Furthermore, some delicate viruses (e.g., coronavirus) degenerate quickly, and the feces from animals suspected of having such an infection must be handled appropriately if meaningful results are to be obtained. It is important that clinicians contact their laboratory for instructions on sample handling.

Assays for bacterial toxins in feces sometimes help implicate specific bacteria as causing diarrhea. There are numerous ELISA tests available for detecting *Clostridum difficile* toxin in human feces; however, the sensitivity of these tests for canine feces appears to be poor. The tissue culture assay for Clostridum difficile toxin in feces is sensitive but only performed in research laboratories. ELISA tests (Clostridium perfringens Enterotoxin Test, TechLab) and reverse passive latex agglutination tests (Oxoid PET-RPLA, Unipath Co.) tests for Clostridium perfringens enterotoxin are available. However, the results of these tests do not clearly correlate with presence or absence of disease. Their value in clinical cases is still being defined.

There are both culture techniques (InPouch TF, BioMed Dianonstics) and polymerase chan reaction (PCR) tests for *Tritrichomonas fetus* in feline feces. The culture technique can be done in the practice and appears to be sensitive and specific; it is more sensitive than direct fecal examination.

# BACTERIAL FECAL CULTURE

Fecal culture is seldom indicated in small animals unless a contagious disease is strongly suspected or other test findings (e.g., endoscopy and biopsy) are nondiagnostic. Specific culture techniques for the detection of each pathogen are recommended. Therefore the clinician should contact the laboratory before submitting feces, informing them specifically what bacteria to attempt to grow and following their instructions regarding the handling of specimens. It is important to remember that fecal culture cannot be used to diagnose small intestinal antibiotic-responsive enteropathy (ARE).

The pathogens most likely to be cultured from feces from small animals are C. perfringens, C. difficile, Salmonella spp., Campylobacter jejuni, Yersinia enterocolitica, and verotoxinproducing strains of Escherichia coli. Confirmation of toxin production of isolates can be performed using PCR techniques or bioassay. Aeromonas spp. and Plesiomonas spp. may also cause diarrhea. Salmonella spp. are best cultured by inoculating at least 1 g of fresh feces into an enrichment medium and subsequently a selective medium specific for Salmonella spp. It is sometimes possible to culture Salmonella from the colonic mucosa. A PCR technique has been used recently in the evaluation of equine feces and may be useful for the evaluation of canine and feline feces. To culture C. jejuni, very fresh feces must be inoculated onto selective media and incubated at approximately 40° C instead of 37° C. If inoculation is to be delayed, special transport media should be used, not routine commercial transport devices (e.g., culturette swabs). PCR testing is available for Campylobacter spp. in canine and feline feces (GI Lab, Texas A&M University). The clinical value is still being defined.

It is important to note that the mere presence of any of these bacteria in an animal's feces does not confirm that they are causing disease. Culture results must be correlated with clinical signs and the results of other laboratory tests.

Candida spp. are occasionally cultured from feces. The finding is often of uncertain significance, but the organisms may cause problems in some animals (e.g., those receiving chemotherapy).

### CYTOLOGIC EVALUATION OF FECES

Fecal cytologic evaluations may identify etiologic agents or inflammatory cells. In this method a thin, air-dried smear is stained with Gram's or a Romanowsky-type stain (e.g., Diff-Quik). The latter identifies cells better than Gram's stain does.

Finding excessive numbers of spore-forming bacteria (e.g., more than 3 to 4 per 1000× field) was once thought to strongly suggest clostridial colitis (see Fig. 33-1). However, the presence of spores is neither specific nor sensitive for clostridial colitis. Finding that the bacterial population is relatively uniform morphologically is of uncertain value, other than to show that the normal bacterial flora is disrupted. However, no comments can be made relative to cause or effect.

Short, curved, gram-negative rods (i.e., "commas" or "seagull wings") are suggestive of campylobacteriosis. The larger spirochetes, which are often plentiful in diarrheic feces, are not *C. jejuni* and are of uncertain pathogenicity. Although cytologic preparations are not critically analyzed in diarrheic small animals, fecal cytologic analysis for *Campylobacter* spp. is a specific, albeit insensitive, method in people. Fungal organisms (e.g., *Histoplasma capsulatum*, *Cyniclomyces guttulatus Candida* spp.) are rarely found by fecal examination; cytologic examination of mucosal scrapings or histologic examination of biopsy specimens is usually necessary to diagnose histoplasmosis.

The finding of leukocytes in feces indicates the presence of a transmural colonic inflammation instead of just a superficial mucosal inflammation. However, a definitive diagnosis of a particular cause is not possible.

# RADIOGRAPHY OF THE ALIMENTARY TRACT

Imaging (i.e., radiography) allows structures to be evaluated that cannot be adequately assessed during physical examination (e.g., esophagus, stomach) and may detect abnormalities missed by abdominal palpation (e.g., gastric mass, foreign object, splenic parenchymal mass). Plain radiographs should always be obtained before contrast-enhanced radiographs because (1) the former may yield diagnostic findings, (2) contrast-enhanced radiographs may be contraindicated, and (3) plain radiographs are needed to ensure a correct radiographic technique during the contrast procedure. Contrast-enhanced radiographs may be able to detect abnormalities (e.g., a gastric outflow tract obstruction) that plain radiographs cannot.

Radiographs are generally useful in the diagnostic workup of animals with dysphagia, regurgitation, vomiting, abdominal mass or distention, abdominal pain, or acute abdomen. They are occasionally helpful in animals with constipation, weight loss, or anorexia of unknown cause, but other tests are usually indicated first in such animals and often render imaging unnecessary. Radiographic findings are rarely diag-

nostic in dogs or cats with diarrhea or copious abdominal effusion.

# ULTRASONOGRAPHY OF THE ALIMENTARY TRACT

Ultrasonography may be done in combination with or instead of radiography; however, it is extremely operator dependent. It is often useful in animals with an acute abdomen, abdominal effusion, vomiting, diarrhea, weight loss, or anorexia of unknown cause and also in those with an abdominal mass, distention, or pain. Ultrasonography can be used to identify pancreatitis, infiltrations in various organs, and intussusceptions that radiography misses. Furthermore, effusions, which render radiographs useless, enhance ultrasonographic contrast. Ultrasonography can be more informative than radiography when determining whether an animal with an acute abdomen requires surgery. Finally, ultrasonography can be used to guide the percutaneous aspiration and biopsy of intraabdominal lesions that would otherwise necessitate surgery or laparoscopy.

### **Techniques**

A 5 MHz probe is probably the most utilitarian. Hair is often clipped so that there is no trapped air that could compromise the quality of the image. Fluid can be infused into the abdomen or stomach to improve the evaluation, but this is infrequently needed.

# Findings

The thickness, echodensity, and homogeneity of organs (e.g., liver, spleen, intestine, stomach, mesenteric lymph nodes, masses) may be assessed. Intraparenchymal infiltrates that cannot be detected radiographically may also be found. The particular ultrasonographic findings seen in specific disorders of the alimentary tract are discussed in subsequent chapters dealing with the disorders.

# IMAGING OF THE ORAL CAVITY, PHARYNX, AND ESOPHAGUS

### **INDICATIONS**

Animals with dysphagia, oral pain, halitosis of unknown cause, or a swelling or mass should generallly undergo imaging. If dysphagia of neuromuscular origin is suspected, dynamic studies (i.e., fluoroscopy) are recommended. Ultrasonography can be particularly informative in the evaluation of any infiltrates or masses.

### **Techniques**

Anesthesia is necessary so that animals can be properly positioned for radiographs of the skull. Lateral, dorsoventral (DV), and oblique views are used to detect foreign objects or fractures. Open-mouth ventrodorsal (VD) views and end-on views of the nose may also be helpful. However,

dynamic studies (i.e., fluoroscopy, cinefluoroscopy) are necessary if one is looking for dysphagia of neuromuscular origin. These studies are performed by feeding conscious animals various forms of barium (i.e., liquid, paste, and mixed with food).

### **Findings**

Foreign objects, fractures, bone lysis, soft tissue masses or densities, and emphysema are commonly found. The bone surrounding the tooth roots should be examined for evidence of lysis and the temporomandibular joints for signs of arthritis. It is important to remember to consider the bilateral symmetry of the skull; one side should be compared with the other when evaluating the VID projection. When performing contrast-enhanced or dynamic studies, the clinician should watch for the aspiration of barium, the strength with which the bolus is propelled into the esophagus, and the synchronization of the opening of the cricopharyngeal muscle with the pharyngeal phase of swallowing.

# INDICATIONS FOR IMAGING OF THE ESOPHAGUS

Indications for evaluating the esophagus include regurgitation (including pharyngeal dysphagia), pain when swallowing, unexplained recurrent pneumonia or cough, and thoracic "masses" (seen radiographically) of undetermined origin. A barium contrast—enhanced esophagram is necessary unless plain films reveal the presence of an esophageal foreign object, evidence of esophageal perforation (e.g., a pleural effusion or pneumothorax), or an obvious hiatal hernia. Finding obvious megaesophagus on plain radiographs is usually considered sufficient, but some dogs with megaesophagus on plain radiographs demonstrate normal function when barium is administered. Ultrasonography is seldom useful for dogs and cats with esophageal disease, unless there is a thoracic mass.

### **Techniques**

Liquid barium is the best contrast agent for esophageal studies; it provides excellent detail and, if aspirated, is not as noxious as paste or food. The clinician must be careful not to administer drugs that affect esophageal motility (e.g., xylazine, ketamine, anesthesia). The animal should take several swallows of dilute barium from a syringe, after which right lateral and VD views are quickly obtained. If possible, the clinician should perform fluoroscopy as the animal swallows the barium to assess esophageal motility and look for partial esophageal obstruction, segmental esophageal weakness, gastroesophageal reflux, and esophageal-pharyngeal reflux (i.e., cricopharyngeal incompetence). Radiographs may be taken if a lesion is found fluoroscopically. If fluoroscopy is not available, multiple radiographs (usually lateral projections) are taken in rapid succession, beginning very shortly (i.e., 5 to 10 seconds) after swallowing.

Barium paste is acceptable if liquid is not available. Hypertonic, iodine-contrast agents do not achieve as good a contrast as barium and cause severe problems if aspirated; isotonic water-soluble iodine contrast agents are better. If radiographic studies performed with liquid or paste contrast agents do not detect an abnormality in an animal in which esophageal disease is strongly suspected, the study should be repeated using a mixture of barium and food (both canned food and dry kibble). Such studies may detect partial strictures or muscular weakness not found in previous studies.

If barium is retained in the esophagus but little or none enters the stomach, the animal should be held in a vertical position so that gravity facilitates the migration of barium into the stomach. If barium readily enters the stomach, this indicates that there is no lower esophageal sphincter obstruction. If a hiatal hernia is suspected but not seen, a lateral radiograph of the caudal thorax may be taken while the abdomen is manually compressed. This is done in an attempt to force the stomach to herniate into the thorax so that the hernia can be demonstrated.

If esophageal disease seems likely but is not found by static radiographs, fluoroscopic studies are required. It may be necessary to observe the esophagus for several minutes (or longer) before some abnormalities (e.g., gastroesophageal or esophageal-pharyngeal reflux) occur. In animals with marginal esophageal disease, fluoroscopy may be necessary to document that primary or secondary esophageal waves are present but are either weak or not readily stimulated.

If an esophageal perforation is suspected (e.g., septic pleuritis or mediastinitis, pneumomediastinum or pneumothorax), an isotonic, iodine contrast medium may be used. However, the only purpose of such a study is to localize the perforation. If the clinician already knows where the leakage is likely to be (e.g., there is a bone foreign body in the esophagus), radiographs are of dubious value; exploratory surgery is usually a better option.

### **Findings**

Esophageal dilation, foreign objects, soft tissue densities, spondylosis suggestive of spirocercosis, and hiatal hernia may often be identified on plain films. An air-filled esophagus is not always diagnostic of pathologic esophageal weakness. Although it is tempting to use plain radiograph findings as the basis for the diagnosis of esophageal disease when there is an "obvious" abnormality, it is easy to misinterpret plain films or miss abnormalities that a barium contrastlenhanced study reveals. Even the finding of a dilated, gasfilled esophagus on plain thoracic films does not definitively diagnose "megaesophagus." Rarely, animals with a dilated, air-filled esophagus on plain films are found to have normal esophageal function when evaluated with barium contrastenhanced radiographs (Fig. 29-1). Likewise, the appearance of an accumulation of foodlike material in the classic location for a vascular ring anomaly may be caused by a localized esophageal weakness or a thymic cyst.

Many foreign objects in the esophagus (e.g., bones) can be seen on plain radiographs. However, excellent radiographic technique is necessary because some bones (especially poultry bones) as well as rawhide treats are relatively radiolucent (Fig. 29-2). An esophageal perforation some-

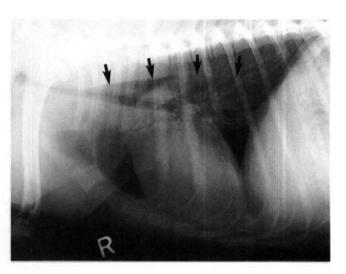

FIG 29-1

times causes pneumothorax, emphysematous mediastinitis, or a pleural or mediastinal effusion.

Contrast-enhanced esophagrams should be considered in animals with suspected esophageal disease and in those with unidentified thoracic masses because many esophageal tumors radiographically resemble pulmonary parenchymal masses (see Fig. 31-5). Contrast-enhanced esophagrams may also show that structures that seemingly involve the esophagus actually do not. An obstruction is suggested on contrast-enhanced esophagrams if the barium column terminates abruptly as it travels caudally; weakness usually causes contrast to be retained throughout the esophagus (Fig. 29-3) unless it is segmental. A partial obstruction is suggested by the retention of barium-impregnated food but not of liquid or paste (see Fig. 31-4).

A barium contrast study may reveal malpositioning (e.g., hiatal hernia; see Fig. 31-2). However, the finding of a properly positioned structure on one study does not ensure that it will stay properly positioned (e.g., some hiatal hernias slide in and out of the diaphragm and may be normally positioned when the radiograph is taken). Gastroesophageal reflux and esophagitis also may be difficult to diagnose radiographically. Barium may adhere to a severely diseased mucosa, but less severe esophagitis may not be detected. In addition, normal dogs may have an episode of gastroesophageal reflux during a contrast study, whereas dogs with pathologic gastroesophageal reflux may not have reflux during a short examination.

If the animal is believed to be regurgitating but the barium contrast—enhanced radiographs are unrevealing, either the assessment of regurgitation is wrong or there is occult disease, in which case reexamination of the esophagus with fluoroscopy or endoscopy or both must be done.

FIG 29-2

**A,** Lateral thoracic radiograph from a dog with a foreign object in the esophagus (arrows). Note the concomitant pleural effusion. A chicken bone had perforated the esophagus, and septic pleuritis was present. (**A** from Allen D, editor: Small animal medicine, Philadelphia, 1991, JB Lippincott.) **B,** Lateral thoracic radiograph from a dog with a rawhide treat in the esophagus. The density representing the bone (arrows) is more diffuse than was seen in **A** and looks more like a pulmonary parenchymal density than a bone.

# IMAGING OF THE STOMACH AND SMALL INTESTINE

# INDICATIONS FOR RADIOGRAPHIC IMAGING OF THE ABDOMEN WITHOUT CONTRAST MEDIA

Indications for plain abdominal radiography may include vomiting, acute abdomen, constipation, abdominal pain, enlargement, distention, or a mass. Plain radiographs are rarely beneficial in animals with a marked abdominal effusion (the fluid obliterates serosal detail) or with chronic diarrhea. Plain radiography is often not as cost-effective when the abdomen can be palpated thoroughly as when the area is difficult to examine (e.g., large or obese animals or animals in pain). In vomiting animals plain abdominal radiographs can be especially helpful in detecting radiodense

foreign objects and alimentary tract dilation resulting from obstruction, foreign objects, or masses.

### **Techniques**

The clinician always should obtain two radiographic views, usually right lateral and VD projections. Cleansing enemas may improve the diagnostic usefulness of radiographs in patients with a great deal of feces; however, a critically ill animal or one with an acute abdomen generally should not have an enema unless plain radiographs show it is necessary.

### **Findings**

Plain abdominal radiographs may detect masses, foreign objects, a gas- or fluid-distended hollow viscus, misshapen or emphysematous parenchymal organs, pneumoperito-

Note that barium is retained throughout the length of the esophagus (arrows). **B,** Lateral thoracic contrast-enhanced radiograph of a dog with an esophageal obstruction caused by a vascular ring anomaly. The column of barium stops abruptly (short arrow) in front of the heart, a finding characteristic of a persistent fourth aortic arch. A filling defect is also displacing barium in the dilated portion of the esophagus (long arrows). (Courtesy Dr. Phillip F. Steyn, Colorado State University, Fort Collins, Colo.)

neum, abdominal effusions, and displaced organs suggestive of a mass or adhesion.

Gastric outflow tract obstruction is easy to diagnose when there is marked gastric distention (Fig. 29-4). However, if the patient has recently vomited, the stomach may be empty and contracted. Gastric dilation, especially with volvulus, is easily recognized (see Fig. 32-4). Radiodense foreign objects are easily seen, but radiolucent foreign objects are seen only if they are outlined by swallowed air.

Intestinal obstructions are usually easier to diagnose on the basis of plain radiograph findings than are gastric obstructions; obstructed intestines distended with air, fluid, or ingesta are not readily emptied when the patient vomits (unless it is a high, duodenal obstruction). However, intestinal distention (i.e., ileus) may be caused by inflammation (i.e., adynamic or physiologic ileus) as well as obstruction (i.e., mechanical, occlusive, or anatomic ileus). Anatomic ileus (i.e., obstruction) typically produces a nonuniform intestinal distention with a greater degree of distention than is seen with physiologic ileus (Fig. 29-5). If "stacking" of the distended intestines or sharp bends and turns in the dilated intestines are seen, this also suggests anatomic ileus. Lateral radiographs obtained with the animal standing rarely aid in differentiating anatomic from physiologic ileus. Even experienced radiologists occasionally misdiagnose physiologic ileus as representing an obstruction. Thus diseases producing severe inflammation (e.g., parvoviral enteritis) may clinically and radiographically mimic an intestinal obstruction.

Special types of intestinal obstruction are associated with unique radiographic findings. If the entire intestinal tract is uniformly distended with gas (Fig. 29-6) and the clinical signs fit, mesenteric volvulus may be diagnosed. If marked

intestinal distention is found but is very localized and seems out of place (e.g., has herniated), a strangulated or incarcerated intestinal obstruction (see Fig. 33-9) should be considered.

Linear foreign bodies rarely produce gas-distended bowel loops. Instead, they tend to cause the intestines to bunch together, and sometimes small gas bubbles are present (see Fig. 33-10). This occurs because the intestines "gather" around the linear foreign object as they try to propel it aborad. This "gathering" or "bunching" plus the fact that linear foreign bodies tend primarily to affect the upper small intestines (i.e., duodenum) mean that it is rare that they cause gas-distended loops of bowel. Sometimes pleated (i.e., "accordian-like") intestines can be seen on plain radiographs (see Fig. 33-10).

It is difficult to determine the thickness of intestines on plain radiographs. Animals with diarrhea and an increased amount of intestinal fluid are often misdiagnosed as having thickened intestinal walls.

Decreased serosal contrast is due to either lack of fat or excessive abdominal fluid (see Chapter 36). Displacement of an organ (Fig. 29-7) often means that there is a mass present. Pneumoperitoneum is diagnosed if both the thoracic and abdominal surfaces of the diaphragm or the serosal surfaces of the liver, stomach, or kidneys are easily seen (see Fig. 34-1, *A*). Pneumoperitoneum may also be documented by the finding of only a few gas bubbles in the peritoneal cavity (see Fig. 34-1, *B*).

# INDICATIONS FOR ULTRASONOGRAPHY OF THE STOMACH AND SMALL INTESTINES

Ultrasonography usually reveals almost any soft tissue change that plain radiographs detect in addition to infiltrations that

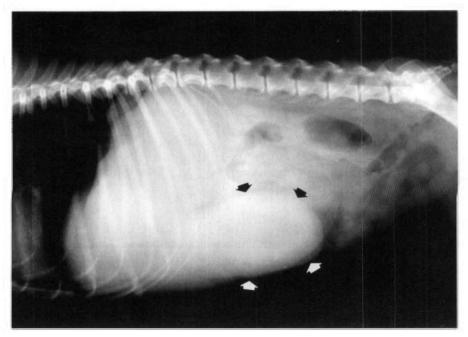

FIG 29-4

Note the lesser degree of small intestinal distention compared with that in **A.** The large gas-filled structure is the gastric pylorus (arrows). (Courtesy Dr. Kenita Rogers, Texas A&M University, College Station, Tex.)

radiographs cannot detect. Ultrasonography is particularly useful for detecting intussusceptions, pancreatitis, abdominal infiltrative disease, and small amounts of effusion not seen radiographically; for evaluating the hepatic parenchyma; and for identifying abdominal neoplasia in animals with a substantial effusion. Ultrasonography is much more revealing than radiography in animals with minimal body fat that have little or no radiographic contrast in the abdomen. However, very dehydrated animals may be difficult to image,

and it is easy to miss small foreign objects (especially in the stomach if there is food and gas present). Ultrasonography will not detect bony changes and modest microhepatica that are easily detected by radiographs. The skill of the ultrasonographer determines the usefulness of the technique.

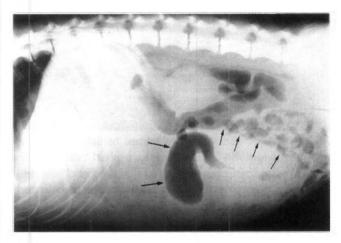

### **Technique**

Before ultrasonography is performed, the abdominal hair usually should be clipped to improve the quality of the

#### FIG 29-6

Lateral abdominal radiograph from a dog that had an acute onset of vomiting, abdominal pain, and shock. There is a uniform intestinal distention that is not as great as that in Fig. 29-5, A. However, distention is more than that seen in Fig. 29-5, B. Some intestinal loops have assumed a vertical orientation (arrows), which suggests the existence of an obstruction. This dog had a mesenteric volvulus. (Courtesy Dr. Susan Yanoff, U.S. Military.)

#### FIG 29-7

Lateral abdominal radiograph from a dog with a large granuloma caused by pythiosis. Small intestinal loops are displaced dorsally and caudally (small arrows). The border of the mass is not discernible except where it displaces small intestinal loops. The finding of a dilated intestinal loop (long arrows) is consistent with obstruction.

examination. This is not necessary in animals with minimal hair. Because air in the stomach or intestines limits the usefulness of ultrasonography, exercise, drugs (e.g., some narcotics) that cause hyperventilation, and enemas should be avoided before the examination.

# **Findings**

Ultrasonography should detect almost any soft tissue change that plain radiographs detect, plus gastric and intestinal infiltrates (Fig. 29-8, A), intussusceptions (Fig. 29-8, B), enlarged lymph nodes (Fig. 29-8, C), masses (Fig. 29-8, D), some radiolucent foreign objects, and small amounts of free peritoneal fluid that radiographs cannot detect. If tissue infiltrates are found, they can sometimes be aspirated by the fine-needle technique.

## INDICATIONS FOR CONTRAST-ENHANCED GASTROGRAMS

Contrast-enhanced gastrography is principally performed in vomiting animals when ultrasound studies and plain abdominal radiographs are unrevealing. It is primarily used to detect a gastric outflow tract obstruction, gastric masses/foreign bodies, and gastric motility problems.

# **Technique**

The animal should not be allowed to eat for at least 12 hours (preferably 24 hours) before the procedure, and feces should be removed with enemas. Plain radiographs should be obtained immediately before the contrast-enhanced films to verify that the abdomen has been properly prepared and the radiographic technique is correct and to determine whether the diagnosis cannot be made on the basis of the plain radiographic findings. Liquid barium sulfate is then administered orally (8 to 10 ml/kg in small dogs and cats and 5 to 8 ml/kg in large dogs). Iohexol can be administered orally (i.e., 700 to 875 mg I/kg, which is about 11/4 to 11/2 ml/kg). The agent should be administered via a stomach tube to ensure adequate gastric filling and optimal evaluation of the stomach. The animal should not receive motility-altering drugs (e.g., xylazine, parasympatholytics), which delay outflow.

Immediately after barium administration, radiographs are taken in the left and right lateral plus DV and VD projections. Radiographs in the lateral and DV projections should be obtained again at 15 and 30 minutes and perhaps also at 1 to 3 hours. The right lateral view causes barium to pool in the pylorus, the left lateral view causes it to pool in the gastric body, the DV view causes it to pool along the greater curvature, and the VD view allows better evaluation of the pylorus and antrum. Double-contrast gastrograms provide more detail than single-contrast gastrograms. They are performed by administering barium via a stomach tube, then removing most of the barium through the same tube and insufflating the stomach with gas until it is mildly distended.

If available, fluoroscopy is best performed immediately after administration of the barium. It can be used to evaluate gastric motility, gastric outflow, and the maximal opening size of the pylorus. If the animal is fed barium mixed with food (only recommended if gastric outflow tract obstruction is suspected despite normal liquid barium study findings), gastric emptying will be markedly delayed compared with that seen when the animal is fed liquid barium.

### **Findings**

Gastric emptying is considered delayed if liquid barium does not enter the duodenum 15 to 30 minutes after administration or if the stomach fails to almost completely empty a

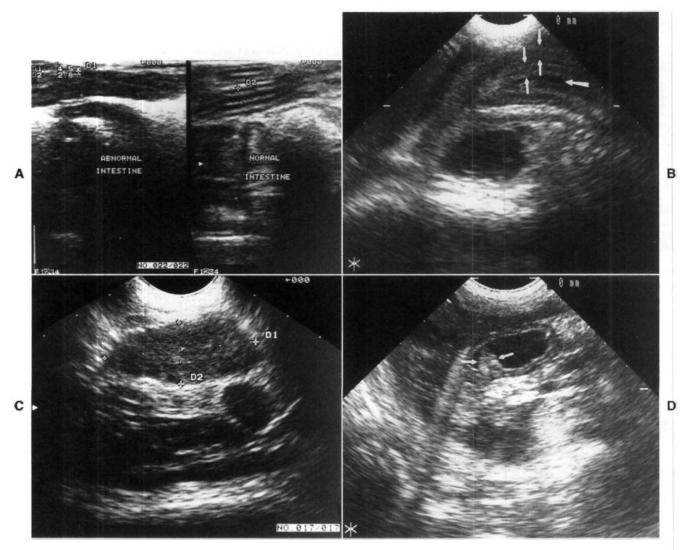

FIG 29-8

**A,** Ultrasonographic image of two sections of small intestine from a cat with an alimentary tract lymphoma. The normal intestine on the right is 2.8 mm thick (see the two "+'s" noted as D2), whereas the abnormal intestine on the left is 4.5 mm thick (D1) because of neoplastic infiltrates. **B,** Ultrasonographic image of an ileocolic intussusception that was not obvious on plain abdominal radiographs. There are two intestinal walls (small arrows) seen on each side of the lumen (large arrow). **C,** An enlarged mesenteric lymph node in a dog caused by lymphoma, seen by ultrasonography. The lymph node was not detected on radiographs or by abdominal palpation. **D,** Ultrasound image of the gastric antrum from a dog with benign gastric polyps. One polyp can be seen (arrows) protruding into the gastric lumen. (Courtesy Dr. Linda Homco, Cornell University, Ithaca, N.Y.)

liquid barium meal in 3 hours (see Fig. 32-2). Luminal filling defects (e.g., growths and radiolucent foreign objects), ulcers, pyloric lesions preventing gastric emptying, and infiltrative lesions may be seen using this method (see Fig. 32-2, *C*). However, normal peristalsis, ingesta, or gas bubbles may resemble an abnormality; therefore a change must be seen on *at least* two separate films before the clinician can diagnose disease.

Contrast-enhanced gastrograms are not as sensitive as endoscopy for detecting gastric ulceration, and they cannot detect erosions. Ulcers are documented radiographically if barium is seen to enter the gastric or duodenal wall or if a persistent spot of barium is identified in the stomach long after the organ has emptied itself of the contrast agent (see Fig. 32-6). The duodenum should be scrutinized in a search for constrictions and infiltrative lesions because many vomiting animals have disease there (e.g., inflammatory bowel disease, tumors) rather than in the stomach (see Chapter 33).

# INDICATIONS FOR CONTRAST-ENHANCED STUDIES OF THE SMALL INTESTINE

Vomiting is the principal reason for performing contrast studies of the upper small intestine. Contrast-enhanced radiographs are particularly useful for distinguishing anatomic from physiologic ileus. Orad obstructions are easier to demonstrate than aborad ones if the contrast medium is administered orally. If a very aborad obstruction is suspected (e.g., ileocolic intussusception), a barium enema (or preferably ultrasonography) is often better than an upper gastrointestinal contrast series. Although linear foreign objects usually produce subtle findings on plain radiographs, they often cause a classic "pleating" or "bunching" of the intestines to be seen on contrast films (see Fig. 33-10, *C*).

Animals with diarrhea seldom benefit from contrast studies of the intestines because normal radiographic findings do not exclude the presence of severe intestinal disease, and even if radiographic findings indicate the presence of infiltrative disease, it is still necessary to obtain a biopsy specimen to determine the cause. Contrast series are sometimes useful if the clinician is trying to decide whether to perform endoscopy or surgery. However, it is usually more cost-effective to perform endoscopy or surgery and skip the contrast-enhanced radiographs.

Use of iodinated contrast agents (preferably iohexol) is reasonable if an alimentary tract perforation is suspected. However, if spontaneous septic peritonitis is strongly suspected, it can usually be definitively diagnosed by ultrasound-guided abdominocentesis and fluid analysis. If ultrasound is unavailable and blind abdominocentesis is unrevealing in such a patient, it is usually better to perform a thorough exploratory laparotomy than contrast-enhanced radiography.

# **Technique**

Liquid barium sulfate is administered as described for contrast-enhanced gastrography. Lateral and VD radiographs should be obtained immediately and then 30, 60, and 120 minutes after barium administration. Additional films are obtained as necessary. The study is completed once contrast has reached the colon. If chemical restraint is absolutely necessary, acetylpromazine may be used. Fluoroscopy is rarely needed for these studies.

Hypertonic iodinated contrast agents are inferior to barium for small intestinal studies because they decrease the intestinal transit time and can cause considerable fluid shifts by osmotically drawing fluid into the gastrointestinal tract. Their potential advantages rarely outweigh the disadvantages. Iohexol is safer and produces better detail than the hypertonic iodinated compounds.

### Findings

In a complete intestinal obstruction, the barium column cannot advance beyond a certain point, and the intestines orad to this point are typically dilated. A partial obstruction may be denoted by delayed passage past a certain point (there may or may not be dilation of the intestines orad to this point) or constriction of the lumen. Because it is easy to overinterpret contrast-enhanced radiographs of the intestines, changes must be seen on *at least* two different films taken at different times before a disease is diagnosed.

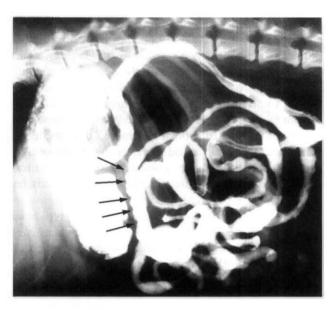

FIG 29-9
Lateral contrast-enhanced radiograph from a dog with duodenal lymphoma. Note the scalloped appearance to the margin of the small intestine (arrows).

"Enteritis" is often incorrectly diagnosed if a fine "brush border" in the lumen is found. However, this finding actually results from the barium normally distributing itself among villi, not from enteritis. Infiltration is denoted by scalloped margins (sometimes called *thumb-printing*); such a pattern (Fig. 29-9) may be seen in the setting of neoplasia (e.g., lymphoma), inflammatory bowel disease, fungal infection (e.g., histoplasmosis), or parvoviral enteritis. However, its absence does not rule out the presence of infiltrative disease. Focal dilations not caused by obstruction (i.e., diverticula) are rare and usually represent a localized neoplastic infiltrate. In rare instances, unsuspected intestinal blind loops or short-bowel syndromes may be detected. Motility problems may cause slowed passage of the contrast through the alimentary tract.

# INDICATIONS FOR BARIUM CONTRAST ENEMAS

If ultrasound and flexible colonoscopy are available, there is seldom any need for barium enemas. If only rigid colonoscopy is available, barium enemas are needed to evaluate the ascending and transverse colon, areas inaccessible to rigid scopes. If colonoscopy is unavailable, a barium enema may be useful for looking for infiltrative lesions (e.g., rectal-colonic neoplasia causing hematochezia), a partial or complete obstruction, or ileocolic or cecocolic intussusception. It can also evaluate the colon orad to a near-complete rectal obstruction to determine whether there are more infiltrative lesions or obstructions besides the one palpated near the rectum.

### **Technique**

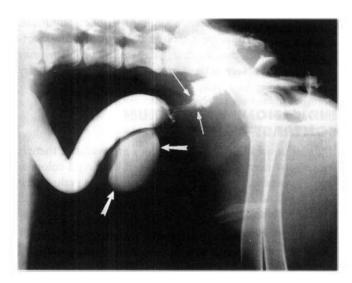

The patient should be fasted for at least 24 hours, and then the colon must be emptied and cleaned by enemas or alimentary tract lavage solutions, or both. The animal should be anesthetized and a balloon-tipped catheter placed in the colon. The balloon is then inflated so that barium cannot leak out the rectum. Approximately 7 to 10 ml of liquid barium/kg at body temperature is infused into the colon until it is uniformly distended, and lateral and VD radiographs are obtained. The colon may then be emptied of barium and insufflated with air to achieve a double-contrast barium enema, which provides greater detail. If too much barium is administered, the ileum may fill with the contrast agent, obscuring colonic detail and making the study less useful.

### **Findings**

Barium enemas unreliably detect mucosal disease (i.e., ulcers, inflammation). If the animal has been properly prepared, these enemas can reveal intraluminal filling defects representing ileocolic or cecocolic intussusception (see Fig. 33-11), proliferative colonic neoplasia (e.g., polyps, adenocarcinoma), extraluminal compression denoted by smooth-surfaced displacement of the barium from the colonic lumen, and infiltrative disease (i.e., a roughened, partial obstruction or an "apple core" lesion) (Fig. 29-10). However, it is imperative that a change be found on *at least* two films to ensure that it is not an artifact.

### PERITONEAL FLUID ANALYSIS

Fluid analysis is discussed in detail in Chapter 36. The fluid is obtained by performing abdominocentesis with a syringe and needle. If this technique fails, a multifenestrated

### FIG 29-10

Lateral view of a dog that had a barium enema. There is circumferential narrowing with roughened borders (thin arrows) that is in distinction to the rest of the colon. This dog had infiltrative adenocarcinoma, which caused an obstruction. The urinary bladder is also seen as a result of the previous contrast procedure (thick arrows).

catheter (e.g., a dialysis catheter, a sterile teat cannula, or an 18-gauge cephalic catheter with additional holes cut with a scalpel) may be successful. It is sometimes best to allow fluid to drain out of the catheter without applying negative pressure.

If peritoneal inflammation is suspected but abdominal fluid cannot be retrieved, a diagnostic peritoneal lavage may be performed. In this method a sterile catheter (preferably with multiple fenestrations) is inserted into the abdomen and warm, sterile physiologic saline solution (20 ml/kg) is administered rapidly. The abdomen is massaged vigorously for 1 to 2 minutes, and then some of the fluid is aspirated. The aspirate is evaluated cytologically.

# **DIGESTION AND ABSORPTION TESTS**

Exocrine pancreatic function may be tested by measuring fecal proteolytic activity (not recommended), fat absorption with and without pancreatic enzymes (not recommended), or serum TLI (recommended).

Fat absorption testing is simple but of questionable sensitivity and specificity. It is no longer recommended. The reader is referred to prior editions of this text for a description of the test and interpretation.

Serum TLI is the most sensitive and specific test for EPI and is convenient (i.e., submit 1 ml of refrigerated serum obtained after an overnight fast) and readily available. The TLI assay detects circulating proteins produced by a normally functioning exocrine pancreas and is even valid in animals receiving pancreatic enzyme supplements orally. Pancreatitis, renal failure, and severe malnutrition may increase the serum TLI concentrations, but this rarely causes results to be misinterpreted. However, if EPI is caused by obstruction of the pancreatic ducts (apparently rare) as opposed to acinar cell atrophy or destruction (common), the serum TLI test may not detect maldigestion. In such cases, a quantitative fecal proteolytic assay is required.

Normal dogs have serum TLI activities of 5.2 to 35  $\mu$  g/L. Values of less than 2.5  $\mu$ g/L confirm a diagnosis of EPI. Normal cats have higher values (28 to 115  $\mu$ g/L). The serum TLI assay is primarily indicated in dogs with chronic small intestinal diarrhea or chronic weight loss of unknown origin. Because feline EPI is rare, the test is seldom necessary in cats. Although principally used to detect EPI, serum TLI values substantially greater than normal are suggestive of pancreatitis.

# SERUM CONCENTRATIONS OF VITAMINS

Serum concentrations of cobalamin and folate are sometimes helpful in animals with chronic small intestinal diarrhea or chronic weight loss. These tests may provide evidence of severe small intestinal mucosal disease. Dietary cobalamin is absorbed in the intestine, principally the ileum. When ARE is present, bacteria sometimes bind cobalamin and prevent

its absorption, decreasing the serum concentrations. Cobalamin concentrations are usually decreased in dogs with EPI, possibly because of the high incidence of ARE in such animals. Severe mucosal disease, especially in the region of the ileum, may also cause serum cobalamin concentrations to be decreased, ostensibly because of malabsorption of the vitamin. Perhaps the major indications for measuring serum cobalamin are to look for evidence of intestinal disease in patients with weight loss of uncertain cause and to better define cats with known small intestinal disease (cobalamin-deficient cats can experience metabolic complications). If the serum cobalamin is low in a patient with weight loss of unknown cause, it is likely that small intestinal disease is responsible. B-complex vitamin supplementation may cause an increased serum cobalamin concentration.

Dietary folate is absorbed in the small intestine. If there are many bacteria in the upper small intestine, these sometimes synthesize and release folate, causing the serum concentrations to be increased. Likewise, severe intestinal mucosal disease may decrease absorption, causing lower serum concentrations. B-complex vitamin supplementation may increase serum folate concentrations.

Because bright light degrades cobalamin, samples should be frozen and kept in the dark during storage and transport. The specificity of decreased serum cobalamin and increased folate concentrations for ARE is questionable.

# OTHER SPECIAL TESTS FOR ALIMENTARY TRACT DISEASE

Antibodies to acetylcholine receptors should be measured if the clinician is looking for a cause of dysphagia or esophageal weakness that could be of neuromuscular origin (see p. 422). Serum is obtained and sent to a laboratory that can perform a validated assay for the species being evaluated. Increased titers to such antibodies are strongly suggestive of myasthenia gravis, even if there are no systemic signs. False-positive results are rare. Testing can be done by Dr. Diane Shelton (Comparative Neuromuscular Laboratory, Basic Science Building, University of California at San Diego, La Jolla, CA 92093-0612).

Measurement of antibodies to 2M muscle fibers can be helpful in dogs with suspected masticatory muscle myositis (see p. 420). These antibodies are typically not found in dogs with polymyositis, whereas most dogs with masticatory myositis have them. Serum is required for the test and can be sent to Dr. Diane Shelton for testing.

Serum gastrin concentrations are measured in animals with signs suggestive of gastrinoma (i.e., chronic vomiting, weight loss, and diarrhea in older animals, especially if there is concurrent esophagitis or duodenal ulceration). Gastrin stimulates gastric acid secretion and is trophic for the gastric mucosa. Serum for assay of gastrin is harvested from an animal after an overnight fast and rapidly frozen. The serum gastrin concentration may be increased in animals with gastrinoma, a gastric outflow tract obstruction, renal failure,

short-bowel syndrome, or atrophic gastritis and in those receiving antacid therapy (e.g.,  $H_2$ -receptor antagonist and proton pump inhibitors). Resting serum gastrin concentrations may vary, with occasional values in the normal range in animals with gastrinoma. Provocative testing should be considered in dogs strongly suspected of having gastrinoma but with normal baseline serum gastrin concentrations (see Chapter 52).

Testing for urease activity in gastric mucosa is sometimes done if the clinician is looking for *Helicobacter* sp. in the stomach. This bacteria has strong urease activity. To perform this, one or preferably two fresh pieces of gastric mucosa are placed into urease agar and observed for up to 24 hours. If these urease-producing bacteria are present, their enzyme will split the urea in the agar into ammonia and the pH indicator in the agar will change from amber to pink (sometimes this occurs within 15 minutes). Tubes of urease agar may be obtained from microbiologic supply houses. There are also special kits designed to detect *Helicobacter* spp. In dogs and cats there is no good evidence that this test is more advantageous than special staining (e.g., Warthin-Starry) of multiple gastric biopsy specimens.

Intestinal permeability testing can be performed, and finding increased permeability seems to be a reliable marker of small intestinal disease. However, at this time it is impossible to diagnose a patient with increased small intestinal permeability as having a particular disease. Currently, the major value to such testing seems to be (1) determining that a patient with clinical signs of uncertain cause has small intestinal disease and (2) evaluating response to therapy in difficult-to-manage patients. This test is seldom done in clinical cases.

Fecal alpha-1 protease inhibitor can be measured in feces and is a marker for gastrointestinal protein loss. Clinically, this test is rarely indicated but could be helpful when trying to distinguish whether hypoalbuminemia is at least partly due to a protein-losing enteropathy in a patient with known renal protein loss or hepatic insufficiency.

Tests for *Pythium insidiosum* are available. ELISA tests for antibodies and PCR testing for antigen can be done at Louisana State University (Dr. Amy Grooters, College of Veterinary Medicine, Lousiana State University, Baton Rouge, LA 70803).

### **ENDOSCOPY**

Endoscopy is often cost-effective if radiographic and ultrasonographic findings have been nondiagnostic in animals with chronic vomiting, diarrhea, or weight loss. It permits rapid exploration of selected sections of the alimentary tract and mucosal biopsy without the need for a thoracotomy or laparotomy. Although excellent for detecting morphologic changes (e.g., masses, ulcers, obstruction), it is insensitive for revealing abnormal function (e.g., esophageal weakness).

Rigid endoscopy is easier to perform and less expensive than flexible endoscopy, and it can provide excellent biopsy

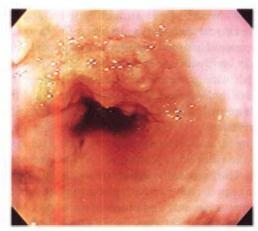

FIG 29-11
Endoscopic view of a polypoid mass in the esophagus of a Chow. This represents an adenocarcinoma.

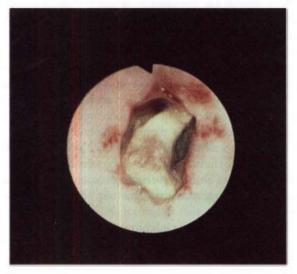

FIG 29-12
Endoscopic view of the esophagus of a dog with a chicken neck bone lodged in it. The bone was ultimately removed with a rigid scope and alligator forceps.

samples. Flexible endoscopes can be used to examine structures that cannot be inspected with a rigid endoscope. Flexible instruments are expensive, and it takes time to become proficient in their use. In addition, one is limited by how far the instrument can be advanced. Furthermore, tissue samples obtained through a flexible endoscope may have artifacts or may be too small to yield diagnostic findings unless the clinician's technique is excellent.

Esophagoscopy is useful in looking for esophageal tumors (Fig. 29-11), foreign objects (Fig. 29-12), inflammation (Figs. 29-13 and 29-14), and obstructions caused by cicatrix (Fig. 29-15). Foreign objects and cicatrix are preferentially treated endoscopically. Esophagoscopy may also show partial obstructions not detected by contrast esophagrams. It is important in such procedures to enter the stomach and retroflex the scope's tip to view the lower esophageal sphinc-

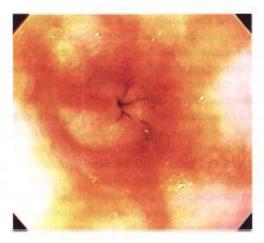

FIG 29-13
Endoscopic view of the lower esophageal sphincter of a dog with moderately severe reflux esophagitis secondary to vomiting. Note the hyperemic areas.

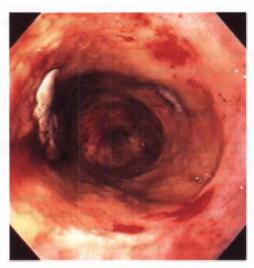

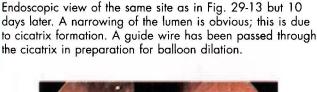

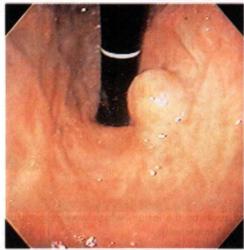

FIG 29-14

ter area to detect leiomyomas (Fig. 29-16) or other easily missed lesions. The esophageal lumen is covered with squamous epithelium, which cannot be pulled off with typical flexible endoscopic forceps. Therefore, if esophageal mucosal biopsy specimens are desired, flexible endoscopes are typically inadequate unless the distal feline esophagus is being biopsied or there is a tumor.

Although esophagoscopy may occasionally detect esophageal weakness (Fig. 29-17), it is not sensitive for detecting this and other selected disorders (e.g., diverticula). Not all foreign objects can be safely removed endoscopically, and the clinician must guard against rupturing a diseased esophagus while trying to extract a foreign object. Finally, care must be taken to avoid creating a potentially fatal gastric distention in patients with esophageal strictures and a fatal

View of the lower esophageal sphincter (as seen from the stomach) of a dog with a leiomyoma. This lesion was causing vomiting and regurgitation and would easily have been missed if a careful, methodical examination had not been carried out.

tension pneumothorax in animals with an esophageal perforation.

Rigid endoscopy is often more useful than flexible endoscopy in removing esophageal foreign objects. The rigid endoscope can protect the esophagus during extraction of the object, and it allows the use of rigid forceps that can grasp the foreign object more tightly. Care must be taken to maintain the animal's esophagus as straight as possible when using a rigid endoscope. If a flexible endoscope is used, it is often helpful to pass it through a rigid scope or tube that has been passed through the cricopharyngeal sphincter; this

FIG 29-17 Endoscopic view of a dog with a megaesophagus. Note that the lumen is dilated and there is substantial food material accumulation.

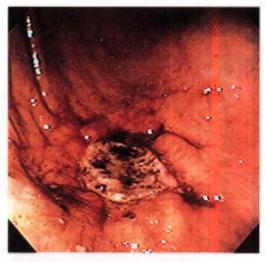

FIG 29-18 Endoscopic view of a gastric ulcer on the greater curvature in a Chow. Note that it is obvious that the mucosa is eroded to the level of the submucosa.

may facilitate passage of the foreign object through the sphincter.

Gastroduodenoscopy and biopsy are indicated in selected animals with vomiting, apparent upper gastrointestinal blood loss, apparent gastroduodenal reflux, or small intestinal disease. It is more sensitive and specific than radiography for detecting mucosal ulcers (Fig. 29-18), erosions (Fig. 29-19), tumors (Fig. 29-20), and inflammatory lesions (Figs. 29-21 to 29-23). Endoscopy is also quicker and less stressful to the animal than exploratory laparotomy. Many foreign objects in the upper gastrointestinal tract (Fig. 29-24) can be removed using endoscopy, and multiple biopsy specimens can be obtained. Occasionally, unexpected diagnoses (e.g., Physaloptera infection; Fig. 29-25) may be found. It may be

Endoscopic view of the gastric mucosa of a dog's stomach that has obvious bleeding. This dog had received nonsteroidal drugs, and the bleeding represented erosions that could not be detected with radiographs or ultrasonography. (From Fossum T, editor: Small animal surgery, St Louis, 1997, Mosby.)

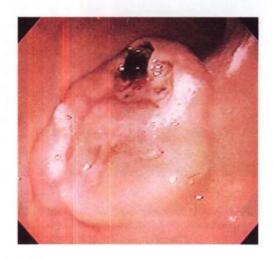

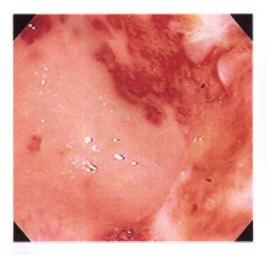

FIG 29-20

necessary to use endoscopes with outer diameters of 9 mm or less in dogs and cats weighing less than 4 to 5 kg. Whenever possible, a scope with a 2.8-mm biopsy channel should be used to obtain larger specimens and allow the use of better foreign object retrieval devices.

The stomach must be as empty as possible when gastroduodenoscopy is performed, which usually necessitates at least a 24-hour fast; many animals undergoing gastroscopy may not empty their stomachs as rapidly as they normally would. During the procedure the stomach must be adequately inflated with air to allow thorough evaluation of its mucosa. Suction must be available to remove secretions or

air. The endoscopist must inspect the mucosa methodically to keep from missing lesions. It is particularly easy to miss lesions (e.g., ulcers or *Physaloptera*) just inside the pylorus. Biopsy specimens of the gastric and duodenal mucosa should always be obtained because normal findings seen on visual examination do not rule out the presence of severe mucosal disease. Like esophagoscopy, gastroscopy is not sensitive in identifying functional problems (i.e., gastric hypomotility).

Proctoscopy or colonoscopy is indicated in dogs and cats with chronic large bowel disease unresponsive to appropriate dietary, antibacterial, or anthelmintic therapies as well as those that are losing weight or are hypoalbuminemic. Colonoscopy is more sensitive and definitive, yet comparable in cost to plain and contrast-enhanced radiography. Proctoscopy is used in animals with obvious rectal abnormalities (e.g., stricture felt on digital rectal examination). Rigid

FIG 29-26

biopsy forceps obtain excellent tissue samples, which allows the identification of most lesions, including submucosal ones. Biopsy instruments used with flexible endoscopes do not obtain as deep a biopsy specimen but are adequate for obtaining specimens from mucosal lesions.

Proctoscopy and colonoscopy are easier to perform, require less animal restraint, and do not always require the more expensive flexible equipment demanded by other endoscopic procedures. The colon must be clean to allow proper inspection of the mucosa. All food should be withheld for at least 24 and preferably 36 hours before the procedure, a mild laxative (e.g., bisacodyl) should be administered the night before the procedure, and several copious warm water enemas should be given the night before and the morning of the procedure. Proctoscopy requires less cleaning than colonoscopy. Commercial intestinal lavage solutions (e.g., GoLytely, Colyte) clean the colon better than enemas and are particularly useful in larger dogs, those that will be undergoing ileoscopy (which necessitates a very clean ileocolic area), and animals in pain that resist enemas. The lavage solution is usually given to the animal twice the night before the procedure and perhaps once the morning of the procedure. In rare cases, it can cause gastric dilation or volvulus.

Sedation plus manual restraint can often be used instead of anesthesia; however, many animals undergoing colonoscopy have colonic or rectal irritation, and anesthesia is usually preferred. Suction should be available.

Normal colonic mucosa is smooth and glistening, and the submucosal blood vessels can be seen (Fig. 29-26); enema tubes may cause linear artifacts. The colon should distend to a uniform diameter, but it may have bends. If a flexible scope is used, the clinician should identify and inspect the ileocolic valve and the cecum (Figs. 29-27 and 29-28). The clinician should always biopsy the mucosa; normal gross findings do

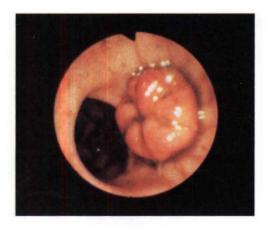

FIG 29-27
Normal ileocolic valve region in a dog. The ileocolic valve is the mushroomlike structure, and the opening below it is the cecocolic valve.

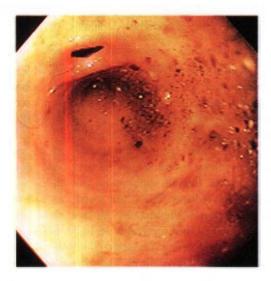

FIG 29-28

not rule out the presence of significant disease. Strictured areas with relatively normal-appearing mucosa are usually caused by a submucosal lesion, in which case biopsying must be aggressive enough to ensure that submucosal tissue is included in the specimen. Cytology can detect histoplasmosis, protothecosis, some neoplasms, and eosinophilic colitis.

An adult or a pediatric human sigmoidoscope is usually adequate for rigid colonoscopy. The tip of the rigid biopsy forceps should have a shearing action (i.e., one part of the tip should fit into the other when it is closed, thus acting like a pair of scissors) instead of a clamshell (also called "double spoon") action in which the edges of the top and bottom jaws simply meet.

Ileoscopy is principally indicated in dogs with diarrhea and in cats with vomiting or diarrhea. It is performed during flexible colonoscopy and requires thorough colonic cleans-

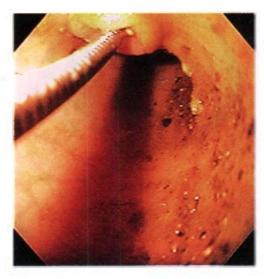

FIG 29-29
Same site as in Fig. 29-28. A biopsy instrument has been blindly passed into the ileum because the scope cannot be advanced through the narrow orifice.

ing so that the ileocolic valve can be visualized. It is difficult or impossible to enter the ileum of most cats (because of size), but one can often pass biopsy forceps through the ileocolic valve and blindly biopsy the ileal mucosa (Fig. 29-29). Ileoscopy can be particularly valuable in diagnosing lymphoma in cats when the duodenal biopsies are nondiagnostic.

# **BIOPSY TECHNIQUES AND SUBMISSION**

# FINE-NEEDLE ASPIRATION BIOPSY

Fine-needle aspiration or core biopsy of enlarged lymph nodes, abdominal masses, and infiltrated abdominal organs may be guided by abdominal palpation or ultrasonography. A 23- to 25-gauge needle is typically used so that any inadvertent intestinal or vascular perforation is insignificant (see Chapter 75).

### **ENDOSCOPIC BIOPSY**

Rigid endoscopy usually provides excellent biopsy samples of the descending colon (i.e., large specimens that include the full thickness of the mucosa, including some muscularis mucosa), but the stomach and small intestine cannot be biopsied with this equipment. Flexible endoscopes can reach more of the alimentary tract, but the tissue samples obtained with these scopes may not always be deep enough to allow submucosal lesions to be diagnosed. Ideally, the tissue to be biopsied is visualized; however, the clinician may pass the biopsy forceps through the pylorus or ileocolic valve and biopsy the duodenum or ileum blindly if the tip of the endoscope cannot be advanced into these areas.

Not all laboratories are adept at processing and interpreting these samples. Endoscopes with 2.8-mm biopsy channel are generally preferred to those with a 2.0- or a 2.2-mm

channel because the larger forceps allow retrieval of substantially larger and deeper tissue samples.

When intestinal or gastric mucosa is biopsied, the tissue sample must be handled carefully to minimize artifacts and distortion. The tissue should be carefully removed from the biopsy forceps with a 25-gauge needle. A squash preparation of one tissue specimen can be evaluated cytologically, and the remaining samples are fixed in formalin and evaluated histologically. The cytology slides should be evaluated by a pathologist familiar with gastrointestinal cytology. Cytologic preparations of the gastric mucosa may show adenocarcinoma, lymphoma, inflammatory cells, or large numbers of spirochetes (see Fig. 32-1). Cytologic studies of the intestinal mucosa may show eosinophilic enteritis, lymphoma, histoplasmosis, or protothecosis, and occasionally giardiasis, bacteria, or Heterobilharzia ova. The absence of cytologic findings suggestive of these disorders does not rule them out, but finding them cytologically is diagnostic.

The laboratory should be consulted regarding the proper way to submit endoscopic tissue sections. In the author's lab, the samples are oriented on the surface of a plastic cassette sponge such that the submucosal side is on the sponge and the luminal side is away from the sponge. The sponge is placed in 10% neutral buffered formalin with the tissues down in the formalin. The clinician should place tissues from different locations in different vials of formalin; each vial should be properly labeled so that the pathologist can correctly identify the area evaluated. Small tissue samples should not be allowed to dry out or be damaged before placement in formalin.

Two common problems with endoscopically obtained tissue samples are that the sample is too small or there is excessive artifact. Lymphomas are sometimes relatively deep in the mucosa (or are submucosal), and a superficial biopsy specimen may then show only a tissue reaction above the tumor, resulting in a misdiagnosis of inflammatory bowel disease. Multiple biopsy specimens should be obtained until there are at least five to eight samples of excellent size and depth (i.e., the full thickness of mucosa). It is important to contact the pathologist and determine whether the quality of the tissue samples was adequate and if the severity of the histologic lesions found is consistent with the clinical signs.

### **FULL-THICKNESS BIOPSY**

If endoscopy is not available, abdominal surgery may be needed to perform gastric and intestinal biopsies. Full-thickness biopsy specimens obtained surgically can have fewer artifacts than those obtained endoscopically; however, the clinician must consider the pros and cons of surgery in a potentially debilitated or ill animal. Endoscopy allows the clinician to direct the biopsy forceps to lesions that cannot be seen from the serosal surface. If surgery is performed, maximal benefit should be obtained from the procedure; the entire abdomen should be examined (i.e., literally from the beginning of the stomach to the end of the colon with all parenchymal organs). Biopsy specimens should be obtained from all obviously abnormal structures. Biopsy specimens of

the stomach, duodenum, jejunum, ileum, mesenteric lymph nodes, and liver (and the pancreas in cats) should be obtained, regardless of how normal these organs appear, unless an obvious lesion is found (e.g., a large tumor). However, it is wise not to assume that a grossly impressive lesion is responsible for the clinical signs; rather, the clinician should perform a biopsy even when the diagnosis seems obvious. Dehiscence is a concern if the serum albumin concentration is less than 1.5 g/dl, but the use of nonabsorbable suture material and serosal patch grafting over intestinal suture lines minimizes the risk. The clinician should consider whether gastrostomy or enterostomy feeding tubes should be placed in emaciated animals before exiting the abdomen.

# **FLUID THERAPY**

Fluid therapy is primarily used to treat shock, dehydration, and electrolyte and acid-base disturbances. Accurately predicting the nature of electrolyte and acid-base changes on the basis of clinical parameters is impossible; therefore serum electrolyte concentrations must be measured. Vomiting gastric contents inconsistently produces a classic hypokalemic, hypochloremic metabolic alkalosis. The loss of intestinal contents classically produces hypokalemia, with or without acidosis, but a hypokalemic, metabolic alkalosis may occur. Vomiting animals are often assumed to be hypokalemic; however, animals with hypoadrenocorticism or anuric renal failure may be hyperkalemic. If electrolytes have not been measured or if fluid therapy must be started before they are available, physiologic saline solution plus 20 mEq potassium chloride per liter is a reasonable therapeutic choice (see Table 30-1), assuming that the fluids are administered at one to two times the maintenance requirement. A lead II electrocardiographic (ECG) tracing may be evaluated to ensure that moderate to severe hyperkalemia is unlikely (see Chapter 55).

It is rarely necessary or appropriate to administer bicarbonate because reexpanding the vascular compartment and improving peripheral perfusion will alleviate lactic acidosis. Bicarbonate is primarily administered in patients with extreme acidosis (e.g., pH < 7.05 or bicarbonate <10 mEq/L) that are in imminent danger of dying. Bicarbonate or lactated Ringer's solution should not be used if alkalosis seems likely (e.g., vomiting of gastric origin).

Parenteral fluid administration is indicated if the animal is significantly hypovolemic or if the absorption of enteral fluids is questionable (e.g., severe intestinal disease, obstruction, vomiting, or ileus). Subcutaneous (SC) fluid administration is acceptable if the animal is not in shock, absorbs the fluids, and accepts repeated SC administration. Multiple SC depots of 10 to 50 ml each are given, depending on the animal's size. Dependent areas should be checked for the presence of unabsorbed fluids before administering more fluid. Severely dehydrated animals may not absorb SC fluids as rapidly as desired, making initial intravenous (IV) administration more effective. IV fluid administration is required in patients that are severely dehydrated or are in shock, even if a venous cutdown is necessary. Intramedullary administration may be used if IV administration is desired but a catheter cannot be established. To do this, a large-bore hypodermic needle or a bone marrow aspiration needle (preferable) can be inserted through the femur (trochanteric fossa), the tibia, the wing of the ilium, or the humerus. Fluids can be administered by the intramedullary route at a maintenance rate or faster. Intraperitoneal administration is acceptable but repletes the intravascular compartment more slowly than IV or intramedullary techniques.

Dogs in shock (e.g., those with tachycardia, poor peripheral perfusion, cool extremities, a prolonged capillary refill time, a weak femoral pulse, and/or tachypnea) may receive 88 ml of isotonic crystalloids per kilogram or more intravenously during the first hour. This "maximum" rate may be exceeded if necessary to reestablish adequate peripheral perfusion; the patient must be closely monitored to determine whether the fluids are being administered appropriately. It is also important to remember that dogs with systemic inflammatory response syndrome (SIRS) initially have brick-red

oral mucous membranes; warm extremities; and a strong, bounding femoral pulse before the signs of classic shock occur. Large dogs in severe shock, such as those with a gastric volvulus, may require two simultaneous 16- to 18-gauge cephalic catheters and IV bags placed in pneumatic compression devices to achieve an adequate flow rate. It is easier to overhydrate cats; the clinician should therefore monitor cats carefully when rapidly administering fluids. In general, the clinician should not exceed 55 ml/kg during the first hour for cats in shock. Lactated Ringer's solution or physiologic saline solution is commonly used for treating shock. However, the clinician must be sure that fluids that are to be administered rapidly for shock do not contain too much potassium because cardiotoxicity can occur.

Hypertonic saline solution (i.e., 7%) may be used to treat severe hypovolemic or endotoxic shock. Relatively small volumes (i.e., 4 to 5 ml/kg delivered over 10 minutes) seem to be as effective as larger volumes of isotonic crystalloids. Hypertonic solutions shift fluid from the intracellular and interstitial compartments into the intravascular compartment and stimulate vascular reflexes. Hypertonic solutions generally should not be used in animals with hypernatremic dehydration, cardiogenic shock, or renal failure. Uncontrolled hemorrhage may also be a contraindication to their use. The clinician may readminister hypertonic saline solution in 2 ml/kg aliquots until a total of 10 ml/kg has been given or until the serum sodium concentration is 160 mEq/ L or more. After administering hypertonic saline solution, the clinician may continue to administer other fluids but at a reduced rate (e.g., 10 to 20 ml/kg/hr) until shock is controlled. A mixture of 7% saline solution plus dextran 70 has a longer duration of action than hypertonic saline solution alone. This combination may be administered at a rate of 3 to 5 ml/kg over 5 minutes. Dextran is rarely associated with allergic reactions or renal failure but should be used carefully or not at all in animals with coagulopathies.

Colloids (e.g., hetastarch) are also useful in treating shock. Like hypertonic saline solution, colloids draw water from the interstitial compartment into the vascular compartment; however, their effects last longer and do not increase the total body sodium load. Relatively small volumes can be administered quickly (i.e., 5 to 10 ml/kg, maximum of 20 ml/kg in 1 day), and the clinician must reduce the subsequent rate of IV fluid administration to prevent hypertension. Colloids should be used with caution in animals with bleeding tendencies.

If it is difficult to maintain peak systolic blood pressures above 80 to 90 mm Hg, vasopressors may be needed. Constant rate infusion of vasopressin has been very effective for this purpose, even when dobutamine and dopamine were unsuccessful.

Approximately 44 to 66 ml of fluid per kilogram of body weight is required daily for maintenance for dogs weighing between 10 and 50 kg, with larger dogs needing less than smaller dogs. Dogs weighing less than 5 kg may need 80 ml/kg/day. It is important to choose the correct fluid to prevent electrolyte imbalances, especially hypokalemia. In general,

General Guidelines for Potassium Supplementation of IV Fluids

PLASMA POTASSIUM CONCENTRATION (mEq/L)	AMOUNT OF KCI TO ADD TO FLUIDS GIVEN AT MAINTENANCE RATES* (mEq/L)
<b>3</b> . <i>7</i> - <b>5</b> .0	10-20
3.0-3 <i>.7</i>	20-30
2.5-3.0	30-40
2.0-2.5	40-60
≤2.0	60-70

<sup>\*</sup>Do not exceed potassium, 0.5 mEq/kg/hr, except in animals in hypokalemic emergencies and then only with constant, close electrocardiogram (ECG) monitoring. Be sure to routinely monitor plasma potassium concentrations whenever administering fluids with more than 30 to 40 mEq of potassium per liter.

potassium should be supplemented if the animal is anorectic or vomiting, has diarrhea, or is receiving prolonged or intense fluid therapy (see guidelines for administration in Table 30-1). The animal should be monitored for the development of iatrogenic hyperkalemia (e.g., ECG or plasma potassium determinations), and no more than 0.5 mEq/kg/h should generally be administered. Oral (PO) potassium supplementation is often more effective than parenteral supplementation if the animal is not vomiting. Cats receiving IV fluids often show an initial decrease in their serum potassium concentrations, even if the fluids contain 40 mEq or more of potassium chloride per liter.

Dehydrated animals not in shock are treated by replacing the estimated fluid deficit. To do this, first the degree of dehydration must be estimated. Prolonged skin tenting is usually first noted at 5% to 6% dehydration. However, any dog or cat that has lost weight may show skin tenting, whereas obese animals and those with peracute dehydration often do not show skin tenting, regardless of the severity of dehydration. Dry, tacky oral mucous membranes usually indicate 6% to 7% dehydration. However, dehydrated, nauseated animals may have moist oral mucous membranes, whereas wellhydrated, panting, or dyspneic animals have dry mouths. Multiplying the estimated percentage of dehydration by the animal's weight (in kilograms) determines the liters required to replace the deficit. This amount is typically replaced over 2 to 8 hours, depending on the animal's condition. Fluid delivery rate should generally not exceed 88 ml/kg/hr. In general, it is better to slightly overestimate rather than underestimate the fluid deficit, unless the animal has congestive heart failure, anuric or oliguric renal failure, severe hypoproteinemia, severe anemia, or pulmonary edema. It is usually easier to harm cats than dogs by excessive fluid administration.

Ongoing losses are typically estimated from the observation of vomiting, diarrhea, and urination; however, it is common to underestimate losses. Weighing the animal regularly is one way to estimate the adequacy of maintenance fluid therapy. A progressive weight loss suggests inadequate fluid therapy. The same scale should always be used to ensure consistent results. A change of 1 lb (0.45 kg) represents approximately 500 ml of water.

The development of inspiratory pulmonary crackles, a gallop rhythm, or edema (especially cervical) indicates that the animal is probably overhydrated. A new heart murmur is not always a sign of overhydration; severely dehydrated dogs with valvular insufficiency may not have an audible murmur until they are volume replete. The central venous pressure is excellent for detecting excessive fluid administration; however, it is rarely necessary to measure it, except in animals with severe cardiac or renal failure and those receiving aggressive fluid therapy. The central venous pressure (CVP) is normally less than 4 cm H<sub>2</sub>O and generally should not exceed 10 to 12 cm H<sub>2</sub>O, even during aggressive fluid therapy. Poor technique will often give falsely high CVP readings.

Oral rehydration therapy makes use of the facilitated intestinal absorption of sodium. The co-administration of a monosaccharide (e.g., dextrose) or amino acid with sodium speeds up sodium absorption and subsequent water uptake. This approach works if the animal can ingest oral fluids (i.e., it is not vomiting) and the intestinal mucosa is functional (i.e., there is reasonable villus function). Absorption primarily occurs in the mature epithelium near the villus tip. Various products for use in people are commercially available, and there are also recipes for making these solutions. Failure to monitor the patient or follow instructions may lead to the development of severe hypernatremia. Some dogs and cats with acute enteritis not caused by severe parvoviral enteritis can receive rehydration fluids orally.

The type of fluid therapy used in hypoproteinemic animals depends on the degree of hypoalbuminemia. Excessive fluids can dilute the serum albumin concentration, causing ascites, edema, diminished peripheral perfusion, or a combination of these. Careful calculation of the fluid needs and ongoing losses is therefore necessary. In animals with severe hypoalbuminemia (e.g., serum albumin of 1.5 g/dl or less), a plasma transfusion (6 to 10 ml/kg of plasma initially) may be considered to improve the oncotic pressure. A common mistake is to give inadequate amounts of plasma. Therefore the serum albumin concentration should be measured 8 to 12 hours after the transfusion to ensure that sufficient plasma was administered. Further, animals with severe protein-losing enteropathies and protein-losing nephropathies rapidly excrete the supplemented protein, making repeated transfusions necessary if the plasma albumin concentration is to be maintained. It can therefore be very expensive to replenish albumin in large, hypoalbuminemic dogs. Human albumin has been used instead of canine plasma and appears efficacious although side effects have been reported. Hetastarch (5 to 20 ml/kg/day) and dextran 70 may be used in place of plasma or albumin. Hetastarch (supplied as a 6% solution) is larger than albumin and therefore may persist in the intravascular space longer than

albumin, thereby helping maintain the plasma oncotic pressure in animals with severe protein-losing enteropathies. If hetastarch is used, the clinician should decrease the rate of fluid administration to prevent hypertension. Sometimes, administering hetastarch results in massive fluid retention and substantial worsening of ascites.

### DIETARY MANAGEMENT

Symptomatic or specific dietary therapy is often important in animals with gastrointestinal tract problems. Symptomatic therapy usually involves the use of bland, easily digested diets, whereas specific therapy typically involves the use of elimination or hypoallergenic diets, diets with a highly restricted fat content, fiber-supplemented diets, or a combination of these.

Bland, easily digested diets are indicated in animals with acute gastritis or enteritis. Such diets are available commercially (Box 30-1). Homemade versions usually consist of boiled poultry or lean hamburger, low-fat cottage cheese, boiled rice, and/or boiled potatoes in some combination. Boiled chicken, turkey, or fish and green beans may be useful in cats. A typical mixture is one part boiled chicken or cottage cheese and two parts boiled potato. The restricted-fat content facilitates digestion. These diets also tend to be low in lactose, which helps prevent maldigestion. Frequent, small amounts of these foods are usually fed until the diarrhea resolves, and then the diet is gradually changed back to the routine one. This diet may be continued after the event is over; however, if a homemade diet is used long-term, it must be nutritionally balanced (especially for puppies and kittens).

These easily digested diets usually also help prevent vomiting because they are low in fat and fiber (both delay emptying) and high in complex carbohydrates. Extremely hyperosmolar diets should be avoided (e.g., do not use concentrated sugar solutions or honey) because they also may delay gastric emptying.

Elimination diets are indicated if a dietary allergy (i.e., an immune-mediated hypersensitivity to a dietary component) or intolerance (i.e., a nonimmune-mediated problem) is sus-

# Examples of Commercial Bland\* Diets

Hill's Prescription Diet i/d lams Eukanuba Low-Residue-Adult Purina CNM EN-Formula Royal Canin Intestinal HE Formula (dogs) Royal Canin Canine Low Fat

Royal Canin Intestinal HE 30 Formula (cats)

This list is a partial list for the purpose of showing examples of such diets. It is not an all-inclusive list of such diets.

<sup>\*&</sup>quot;Bland" refers to easily digestible diets that often contain less fat than is found in many pet foods.

BOX 30-2

### Examples of Homemade, Hypoallergenic\* Diets

1 part boiled white chicken or turkey meat without the skin; 2 parts boiled or baked potato (without the skin)

1 part boiled or broiled white fish without the skin; 2 parts boiled or baked potato (without the skin)

1 part boiled mutton, venison, or rabbit without the skin; 2 parts boiled or baked potato (without the skin)

1 part drained, low-fat cottage cheese; 2 parts boiled or baked potato (without the skin)

A nonflavored vitamin supplement may be given three times per week.

Rice can be substituted for potato, but many dogs and cats seem to digest potato more easily than rice.

These diets are not balanced but are adequate for 3 to 4 months of use in sexually mature animals. If growing animals are being fed such a diet, then a nutritionist must be consulted to balance calcium and phosphorus.

\* Hypoallergenic refers to a diet specially formulated for a given animal, one that does not expose the animal to potential allergens that it has eaten in the past. Therefore the clinician must obtain a careful dietary history to determine what will or will not constitute a hypoallergenic diet for a particular animal.

pected. There is also evidence that such diets may help treat and control antibiotic-responsive enteropathies. These diets may be composed of the same ingredients found in bland diets; however, they must be formulated so that the animal is fed food that it has not eaten before (and hence could not be responsible for causing allergy or intolerance) or food that is very unlikely to provoke allergy or intolerance (e.g., potatoes). Excellent commercial elimination diets are available, or the clinician may suggest a homemade diet. Examples of homemade elimination diets are described in Box 30-2.

Elimination diets that are going to be effective are usually effective within 3 to 4 weeks, although in rare cases patients may require 6 or more weeks before clinical efficacy is evident. It is critical that no other foods or treats be given to the animal during this time (e.g., flavored pills, toys, medications). If the signs resolve during this time, the diet should be continued for at least 4 to 6 more weeks to ensure that it is the diet that is responsible for the animal's improvement and not a spontaneous fluctuation of the disease. If a homemade diet was used, the clinician should try to gradually switch the animal to a commercial diet or balance the homemade diet with appropriate vitamins, minerals, and fatty acids.

Partially hydrolyzed diets (Purina HA; Nestle Purina, Hill's z/d; Hill's Pet Products, Hypoallergenic HP19 Formula [dogs] and Hypoallergenic HP23 Formula [cats]; Royal Canin) have been formulated in an attempt to eliminate proteins large enough to cause immunologic reactions (i.e., make a diet that is hypoallergenic for all animals). Although these diets are not uniformly effective, many dogs and cats with gastrointestinal diseases will have clinical improvement

when eating these diets exclusively. The partially hydrolyzed proteins may also make such diets easier for diseased alimentary tracts to digest and absorb.

Elemental diets (e.g., Vivonex TEN; Novartis Nutrition) are diets in which the nutrients are supplied as amino acids and simple sugars. These diets are hypoallergenic, but more important, they are extremely easy to digest and absorb when there is major small intestinal disease. Diseased intestines have increased permeability, which allows luminal contents to leak into the mucosa. Such leakage may be an important mechanism perpetuating intestinal inflammation. Because the amino acids and simple sugars found in elemental diets do not elicit an inflammatory reaction when they enter the interstitium, they do not contribute to perpetuation of the inflammatory response in the intestines. The elemental diets prepared for people (e.g., Vivonex TEN) typically have less protein than desired for veterinary patients. Therefore protein supplements are usually given when preparing this diet by adding 350 ml of water plus 250 ml of 8.5% amino acids (for injection) instead of 600 ml of water. Adding 1 to 2 ml of a flavored vitamin syrup often makes it palatable. If the animal will not drink this formulation, it may be administered via nasoesophageal tube. These diets are generally reserved for patients that are extremely ill from severe intestinal disease.

Ultra-low-fat diets are indicated in animals with intestinal lymphangiectasia. Because long-chain fatty acids enter lacteals and are reesterified, removing them from the diet therefore prevents the dilation and rupture of lacteals and the subsequent intestinal lymphatic loss. Medium-chain triglycerides (MCTs) were once recommended as supplements to such diets at a dose of 1 to 2 ml/kg of body weight. MCTs appear to be absorbed into the portal blood without going through the lacteals and thoracic duct. They have an unpleasant taste, so very small amounts (e.g., 1 tsp/lb of food) should be added to the diet initially. Otherwise, the animal may refuse to eat the food. Using a highly digestible, ultra-low-fat diet usually eliminates the need for supplementing MCTs; however, MCTs have been used to help very thin animals with severe gastrointestinal disease absorb nutrients and gain weight.

Fiber supplementation may help many dogs and cats with large (and rarely small) intestinal diseases. Although fiber is generally classified as soluble or insoluble, many fibers have characteristics of both. Insoluble fiber is poorly digested or metabolized by bacteria and ultimately produces more stool bulk. Some insoluble fibers apparently normalize colonic myoelectrical activity and help prevent spasms. Soluble fiber can be metabolized by bacteria into short-chain volatile fatty acids, which are trophic to colonic mucosa; it may also slow the absorption of nutrients by the small intestine.

Fiber-enriched diets may ameliorate diarrhea in many animals with large bowel disease (especially those with minimal inflammation) and lessen constipation not caused by obstruction or pain. Such a diet should be fed for at least 2 weeks before assessing efficacy, although most animals that respond do so within the first week. A commercial high-fiber

diet may be used, or fiber may be added to the current diet. Psyllium hydrocolloid (e.g., Metamucil) or coarse, unprocessed wheat bran may be added to the pet's diet in the amount of 1 to 2 teaspoons or 1 to 4 tablespoons per can of food, respectively. Some cats will not eat these diets or fiber supplements; however, canned pumpkin pie filling is effective and usually acceptable to cats; 1 to 3 tablespoons may be given daily. It is important that the animal maintain adequate water intake, lest the increased dietary fiber produce obstipation. If too much soluble fiber is fed, there may be excessive stool, which the owner then mistakes for continued large bowel disease.

# SPECIAL NUTRITIONAL SUPPLEMENTATION

If the animal refuses to ingest adequate calories, special nutritional supplementation is necessary. Daily nutritional requirements should be calculated to avoid underfeeding. Approximately 60 kcal/kg/day is reasonable for the maintenance needs of mature dogs and cats that are not lactating or losing a significant amount of energy or protein. More exact calculations are recommended if the animal has severe disease or ongoing fluid and nutritional losses (Box 30-3).

In some cases, simply sending the animal home, warming the food, or feeding the animal a palatable diet (e.g., chicken baby food for dogs) ensures adequate caloric intake. The clinician can attempt force-feeding by manually placing food in the animal's mouth, although this seldom works in severely anorectic animals. Cyproheptadine (2 to 4 mg per cat) stimulates some cats to eat, especially those with mild anorexia. However, cyproheptadine seldom induces a severely anorectic cat (e.g., one with severe hepatic lipidosis) to ingest adequate calories. Diazepam rarely causes acute feline hepatic failure. Megestrol acetate is an excellent appetite stimulant but occasionally causes diabetes mellitus, reproductive problems, or tumors. Cobalamin injections have been noted to increase appetite in some dogs. Recently, mirtazapine has been used with anecdotal success in dogs (once daily) and cats (every three days). Appetite stimulants are usually less effective in dogs than in cats.

Tube feeding is a more reliable way to ensure that adequate calories are ingested. Intermittent orogastric tube feeding is useful for animals that need nutritional support for only a relatively short time, although it may be used for longer periods in orphaned puppies and kittens. It is typically done two or three times daily, using restraint and a mouth gag. A tube is measured and marked to correspond to the length from the tip of the nose to the midthoracic region. The tube is then carefully inserted through the mouth gag to the premarked point. If the animal coughs or is dyspneic, the tube may have entered the trachea and should be repositioned. To ensure safety, the clinician should flush the tube with water before the warmed gruel is administered. The gruel should be given over several seconds or 1 minute. Because relatively large-diameter tubes can be used, homemade gruels may be administered in this way. The major

### Calculation of Nutritional Needs and Formulations of Total Parenteral Nutrition Solution

Actual body weight =	kg	
Basal Energy Requirement		
30 (weight in kg) + 70 = $\frac{1}{100}$ kcal/day However, if <2 kg or >25 kg, use 70 (weight in kg) <sup>0.75</sup>		
Maintenance Energy Requirement		
Adjustment factors: Cage rest After surgery Trauma Sepsis Severe burn	Dogs (1.25) (1.3) (1.5) (1.7) (2.0)	Cats (1.1) (1.12) (1.2) (1.28) (1.4)
Basal Requirement × Adjustment Factor =		
		kcal/day
Protein Requirement		
4 g/kg in adult dogs 6 g/kg in cats and hypoproteinemic dogs If there is renal failure, use 1.5 g/kg in dogs or 3 g/kg in cats		
		g/day

Solution formulation:				
g of protein necessitates ml of an 8.5% or				
10% amino acid solution (85 or 100 mg of protein/ml, respectively).				
Determine the calories derived from the protein (4 kcal/g of				
protein), and subtract this from the daily caloric needs. Supply the				
remaining calories with glucose and lipid kcal needed.				
Provide at least 10%, and preferably 40%, of caloric needs with				
lipid emulsion. A 20% lipid emulsion has 2 kcal/ml. Do not use in				
lipemic animals; use with caution in animals with pancreatitis.				
ml needed. Provide remainder of calories with 50%				
dextrose, which has 1.7 kcal/ml ml needed.				
Use one half the calculated amount of solution on the first day, and				
increase it to the calculated amount on the second day, if				
hyperglycemia, lipemia, azotemia, or hyperammonemia does not				
occur.				
Either use amino acid solution with electrolytes or add electrolytes				

Either use amino acid solution with electrolytes or add electrolytes so that the solution has sodium, 35 mEq/L; chloride, 35 mEq/L; potassium, 42 mEq/L; magnesium, 5 mEq/L; and phosphate, 15 mmol/L. These concentrations may be adjusted as needed, depending on the animal's serum electrolyte concentrations. Add multiple vitamins and trace elements (especially zinc and copper) that are formulated for parenteral nutrition solutions. For partial (also called peripheral) parenteral nutrition formulation, see Zsombor-Murray et al: Peripheral parenteral nutrition, Comp Cont Educ 21:512, 1999.

disadvantage is the need to physically restrain the animal. Placement of an indwelling tube (discussed in more detail later in this chapter) circumvents this problem.

Nasoesophageal tubes are indicated in animals that need nutritional support and have a functional esophagus, stomach, and intestines. They are easy to place, but they are difficult to maintain in animals that are vomiting. To place them, the clinician first anesthetizes the nose by instilling a few drops of lidocaine solution in one nostril. Then the clinician lubricates a sterile polyvinyl chloride, polyurethane, or silicone tube (the diameter depends on the animal's size, but 5F to 12F is typical) with sterile, water-soluble jelly and inserts it into the ventromedial portion of the nostril. The animal's head is restrained in its normal position, and the tube is inserted until the tip is just beyond the thoracic inlet. If the clinician encounters difficulty in passing the tube, the tip should be withdrawn, redirected, and advanced again. If the clinician is unsure whether the tube is in the esophagus, thoracic radiographs should be obtained or several milliliters of sterile saline solution should be instilled into the tube to see if this provokes coughing.

Tape is applied to the tube to secure it, and then the tape is glued or sutured as needed to the skin along the dorsal aspect of the nose. The tube must not be allowed to touch sensory vibrissae because the animal will not tolerate it. It may be necessary to place an Elizabethan collar on some animals to prevent them from pulling out the tube. Only small-diameter tubes (e.g., 5F) can be used in small dogs and cats, which limits the rate of administration and necessitates the use of commercial liquid diets (Table 30-2) instead of less expensive homemade gruels. The clinician should flush the tube with water after each feeding to prevent occlusion. Long-term acceptance is typical, but rhinitis occurs in some animals.

Some dogs and cats do not tolerate nasoesophageal tubes and repeatedly pull them out. However, they are usually effective for short-term therapy (e.g., 1 to 10 days), and some animals tolerate them for weeks.

DIET	COMMENTS
Osmolite*	Polymeric diet; contains taurine, carnitine, and MCT
CliniCare†	Polymeric diet; contains taurine, but no lactose
Jevity*	Polymeric diet; contains taurine, fiber, carnitine, and MCT
Peptamen‡	Oligomeric diet; contains taurine, carnitine, and MCT
Pulmocare*	Polymeric diet; contains taurine, carnitine, and MCT
Vital HN*	Oligomeric diet; contains MCT
Vivonex T.E.N.§	Elemental diet; high in carbohydrates, low in protein and fat!

MCT, Medium-chain triglyceride.

Pharyngostomy and esophagostomy tubes are indicated in animals with a functional esophagus, stomach, and intestines that require nutritional support but do not tolerate nasoesophageal or intermittent tube feeding. Vomiting may make it difficult to maintain these tubes, but they can be used for weeks to months.

To place a pharyngostomy tube, the clinician anesthetizes the animal and inserts a finger into the mouth so that the tip of the finger is caudal to the epihyoid bone and as dorsal and as close to the cricopharyngeal sphincter as possible. The tip of the finger is then pushed laterally, and a skin incision is made over this spot. Hemostats are used to bluntly dissect through to the pharynx. A soft latex or rubber catheter (18F to 22F, urinary) is then inserted into the opening and into the esophagus. In general, the tip of the catheter should end in the midthoracic esophagus. The tube is secured with traction sutures and the area bandaged. Some inflammation at the stoma is common, and routine cleansing and bandage changes are necessary. Systemic antibiotics are not typically needed. An Elizabethan collar may be used if the animal tries to remove the tube. To remove the tube, the clinician simply cuts the sutures and pulls it out. The opening will close spontaneously over the next 1 to 4 days. Pharyngostomy tubes effectively bypass oral lesions. Advantages of these tubes include easy placement, easy removal, and minimal complications if they have been properly inserted (i.e., they cannot cause peritonitis as gastrostomy or enterostomy tubes can). However, it is easy to place them such that they cause gagging and regurgitation (i.e., if they touch the larynx, especially in cats and small dogs). The clinician should take care not to disrupt vessels or nerves when using scissors or a scalpel during the dissection. Because pharyngostomy tubes are larger than nasoesophageal tubes, homemade gruels can be fed through them.

The placement of esophagostomy tubes is similar to that of pharyngostomy tubes. The animal is placed in right lateral recumbency, the mouth is held open, and a long right-angle hemostat is placed through the cricopharyngeal sphincter. The tip of the hemostat is then forced up to show where to make the incision in the left cervical region. The incision should be made midway between the cricopharyngeal sphincter and the thoracic inlet. The tip of the hemostat is forced up through the esophagus and the nick in the skin; the tip of a feeding tube is then grasped and pulled into the esophagus and out the mouth so that the flared end of the catheter (i.e., where the syringe will be attached) is left protruding from the neck. The distal end of the catheter is then redirected down the esophagus with a rigid colonoscope or other device. Esophagostomy tubes cannot cause gagging but are otherwise similar to pharyngostomy tubes.

Gastrostomy tubes bypass the mouth and esophagus in animals with a functional stomach and intestines. They can also be used when nasoesophageal, pharyngostomy, esophagostomy, or intermittent gastric tubing is unacceptable. Vomiting is not a contraindication. This technique requires surgery, endoscopy, or special devices for proper placement.

<sup>\*</sup> Ross Laboratories, Columbus, Ohio.

<sup>§</sup> Novartis Nutritian, Minneapolis, Minn.

<sup>||</sup> To increase protein content, reconstitute one packet of powder with 350 ml water plus 250 ml of 8.5% amino acids for injection.

Endoscopy is the preferred and safest way to place these tubes percutaneously. The use of dedicated devices for the placement of gastrostomy tubes has made the procedure easier and readily available for clinicians without endoscopes (Fig. 30-1). To place gastrostomy tubes using these devices, the clinician positions the anesthetized animal in right lateral recumbency and surgically prepares the area behind the last rib on the left abdominal wall. The device is then blindly and carefully advanced down the esophagus until the tip is in the stomach and can be seen pushing against the skin behind the last rib. The plunger on the handle is advanced until the trocar in the tip penetrates the skin and can be seen. In the tip of the trocar is a hole in which a suture (e.g., No. 1 or 2 polyamide or other nonabsorbable material) is tied. The clinician then withdraws the device from the animal, bringing one end of the suture with it. In the meantime, another person grasps the other end of the suture firmly so that it cannot be pulled into the stomach. The end of the suture that was brought out through the mouth is now passed retrograde through the sheath of an 18-gauge over-the-needle IV catheter or a disposable pipette tip of similar diameter. Next, one can use either an umbrella catheter specifically designed for use as a gastrostomy tube, or one can modify a mushroom-type catheter (usually 18F to 24F). The latter is prepared by cutting off the syringe end. The clinician then attaches the suture that has been pulled out through the mouth to this end of the catheter, using a needle to pass the suture through the catheter and make a mattress suture pattern. The end of the mushroom catheter tip that has just been attached to the suture is inserted into the flared end of the IV catheter or disposable pipette tip. The other person then begins to pull on the end of the suture where it enters the abdominal wall, thus pulling the cut tip of the mushroom catheter into the stomach. The modified end of the mushroom catheter that was inserted into the disposable pipette tip is thereby pulled out of the stomach through the same hole previously made by the trocar. Traction is placed on the mushroom catheter until the mushroom head is securely placed against the gastric mucosa, which is pulled next to the abdominal wall. (The clinician should take care not to pull the mushroom tip of the catheter out of the stomach.) The catheter is held in place by an outer flange and/or traction sutures (excessive pressure on the gastric mucosa can cause avascular necrosis), and the area is bandaged lightly.

Gastrostomy tubes allow the administration of thick gruels and are often tolerated for weeks to years. Either a homemade gruel or a commercial liquid diet (see Table 30-2) may be used. These tubes must be left in place for at least 7 to 10 days to allow an adhesion to form between the stomach and the abdominal wall, which will prevent gastric leakage into the peritoneal cavity when the tube is removed. They are often used in cats that do not tolerate pharyngostomy, nasogastric, or esophagostomy tubes. The tube should be flushed with water and air after each feeding. Although the entire caloric requirement may be administered as soon as the tube is placed, it is often better to start with one half the

daily requirement and work up to the complete nutritional needs over 1 to 3 days. If the tube becomes plugged, it can sometimes be unplugged by using flexible endoscopy forceps or by instilling a fresh carbonated beverage into the tube. When the tube is to be removed, sufficient traction is applied to the catheter so that the mushroom tip collapses and passes through the stomach and skin incision. The fistula usually closes spontaneously in 1 to 4 days. The major risk of using such tubes is leakage and peritonitis, which are rare but potentially catastrophic. In dogs larger than 20 to 25 kg, gastrostomy tubes are typically placed surgically or sutures are passed through the abdominal wall and into the gastric wall to ensure that the stomach and abdominal wall stay in apposition and form an adhesion that prevents leakage. Improper use of dedicated devices can result in malplacement of the tube and/or perforation of abdominal organs (e.g., spleen, omentum).

Low-profile gastrostomy tubes can be used if a stoma has been previously established by a routine gastrostomy tube. The major advantage of such tubes is that they may replace routine gastrostomy tubes that are disintegrating or have been inadvertently pulled out, and they may be placed without anesthesia or a surgical/endoscopic procedure. Typically, sedation is all that is needed. However, to use the preexisting stoma, the low-profile gastrostomy tube must be placed within 12 hours of removing the old gastrostomy tube, or another tube (e.g., a red latex male urinary catheter) must be inserted into the stoma as quickly as possible to prevent the old stoma from closing.

Enterostomy tubes are indicated in animals with functional intestines when the stomach must be bypassed (e.g., recent gastric surgery). Laparotomy or laparoscopy is generally needed to place these tubes. A 12-gauge needle is used to puncture the antimesenteric border of the intestine, and a sterile 5F plastic catheter is advanced aborally through the needle until approximately 15 cm extends into the intestinal lumen. The 12-gauge needle is removed, and a purse-string suture is placed to prevent the catheter from moving freely. The needle is then used in the same manner to make a pathway for the catheter to exit through the abdominal wall. The antimesenteric border of the intestine is sutured to the abdominal wall so that the sites where the tube enters the intestine and exits the abdomen are opposed. Traction sutures are used to secure the catheter.

The clinician may place a jejunostomy tube by first placing a gastrostomy tube and then inserting a jejunostomy tube through the gastrostomy tube. Next, the clinician directs the jejunostomy tube into the duodenum with a flexible endoscope. Alternatively, the clinician may use a guide wire placed in the duodenum via an endoscope to feed the jejunostomy tube through the gastrostomy tube and into the duodenum.

The small diameter of enterostomy tubes often necessitates the administration of commercial liquid diets (see Table 30-2), which are best infused at a constant rate. The rate necessary to administer daily caloric needs is calculated. A one half-strength feeding solution is administered at one

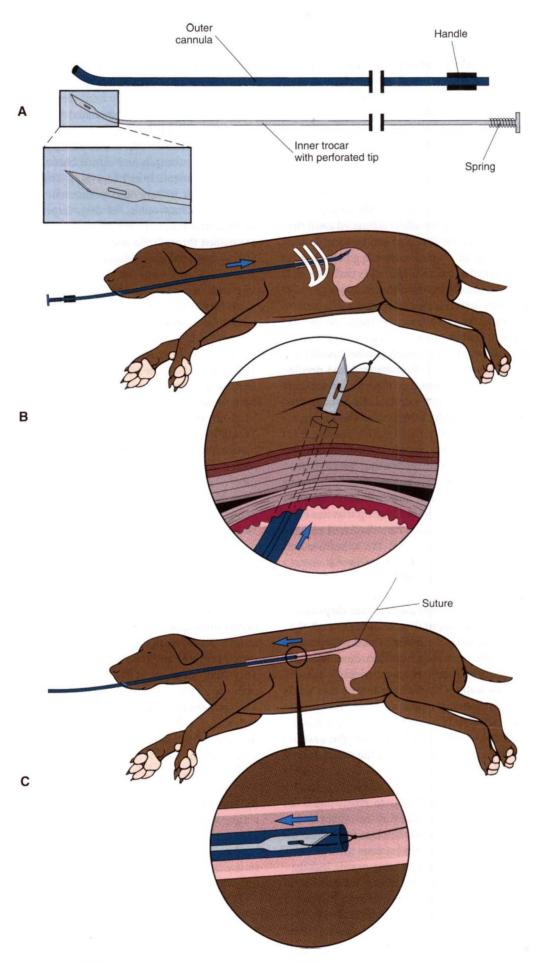

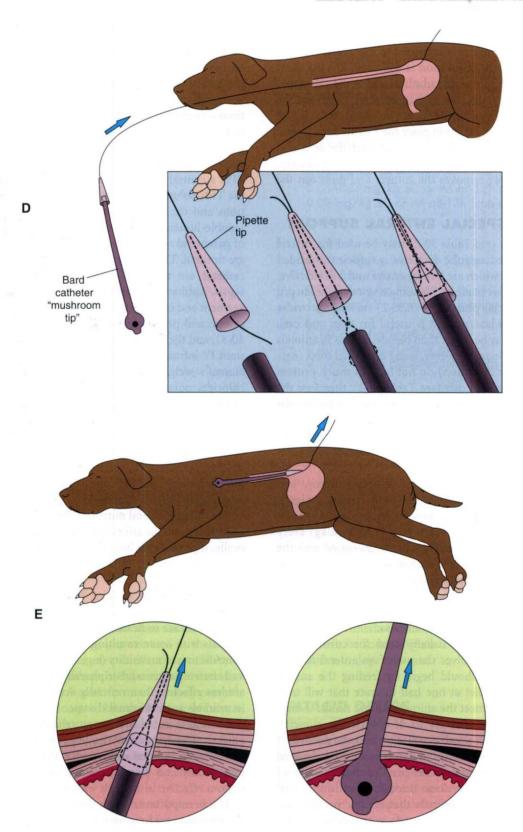

FIG 30-1 For legend see opposite.

# FIG 30-1

The proper way to use a dedicated device to place a gastrostomy tube. **A,** The device consists of a cannula with a handle and a trocar that is passed through the cannula once it is properly positioned. **B,** Proper placement of the device behind the last rib. The trocar is pushed through the cannula until the tip exits the skin such that a suture can be tied onto the tip. **C,** The device and the attached suture are withdrawn through the animal's mouth. **D,** The proper way to use a dedicated device to place a gastrostomy tube. The tip of the suture that exits the mouth is attached to the cut end of a mushroom-tip catheter. **E,** The other end of the suture is pulled so that the tip of the catheter exits the skin. It is pulled until the mushroom tip is snugly against the gastric mucosa and the stomach is held against the abdominal wall. (Reprinted with permission from Fossum T, editor: *Small animal surgery*, St Louis, 1997, Mosby.)

half the calculated rate on the first day. On the second day the rate of administration is increased to the calculated rate, but a one half–strength solution is still used. On the third day a full-strength solution is administered at the calculated rate. If diarrhea occurs, the rate of administration can be decreased or fiber (e.g., psyllium) can be added to the liquid diet. The tube should be left in place for 7 to 10 days, if possible, to allow adhesions to develop around the area and prevent leakage. When enteral feeding is no longer necessary, the clinician simply removes the sutures and pulls out the catheter.

### DIETS FOR SPECIAL ENTERAL SUPPORT

Commercial diets (see Table 30-2) may be used for enteral support. If the feeding tube diameter is sufficient, blended commercial diets, which are less expensive and still effective, can be used. A gruel made by blending one can of feline p/d (Hill's Pet Products) plus 1½ C (0.35 L) of water provides approximately 0.9 kcal/ml and is useful for dogs and cats. Elemental diets may be better than blended gruels in animals with intestinal disease. However, some elemental diets (e.g., Vivonex, Novartis Nutrition) do not have as much protein as desired for dogs and cats (see Table 30-2); therefore the clinician may replace some of the water used in mixing the elemental diet with 8.5% amino acids for injection (e.g., 350 ml water +250 ml 8.5% amino acids). When feeding cats, the clinician must be sure that sufficient taurine is present in the diet.

Nasoesophageal, pharyngostomy, esophagostomy, and gastrostomy tubes are usually used for bolus feeding. Animals that have been anorectic for days to weeks should usually start by receiving small amounts (e.g., 3 to 5 ml/kg) every 2 to 4 hours. The amount is gradually increased and the frequency decreased until the animal is receiving its caloric needs in three or four daily feedings. The clinician should expect to ultimately administer at least 22 to 30 ml/kg at each feeding to most dogs and cats. Larger volumes may be given if they do not cause vomiting or distress.

Enterostomy tubes are usually used for constant-rate feeding, which best involves the use of an enteral feeding pump. The clinician should begin by feeding the animal a one half-strength diet at one half the rate that will ultimately be needed to meet the animal's caloric needs. If diarrhea does not result after 24 to 36 hours, the clinician increases the flow rate to what will ultimately be needed. If diarrhea still does not occur, the diet may then be changed from one half strength to full strength. Constant infusion of these same diets may be done through gastrostomy and esophagostomy tubes in animals that readily vomit when fed food in boluses (e.g., some cats with severe hepatic lipidosis). Animals that are critically ill and vomit readily are believed to potentially benefit from "microalimentation," in which very small amounts of liquid diet (e.g., 1 to 2 ml/h in 30 to 40 kg dogs) are infused into nasoesophageal tubes in an effort to get some nutrition to the intestinal mucosa and prevent bacterial translocation and, ultimately, sepsis.

### PARENTERAL NUTRITION

Parenteral nutrition is indicated if the animal's intestines cannot reliably absorb nutrients. It is the most certain method of supplying nutrition to such animals; however, it is expensive and can be associated with metabolic and infectious complications. There are two types of parenteral nutrition: total parenteral nutrition (TPN) and partial (also called peripheral) parenteral nutrition (PPN). In general, PPN is much more convenient and less expensive than TPN. For TPN a central IV line is dedicated to the administration of the TPN solution only (i.e., the piggybacking of other solutions and the obtaining of blood samples are forbidden). Double-lumen jugular catheters allowing the administration of parenteral nutrition and fluids through the same catheter are optimal. The aseptic placement and management of the catheter are the best protection against catheter-related sepsis. Antibiotic prophylaxis does not replace proper management and is ineffective in preventing infections. The daily caloric and protein requirements are determined (see Box 30-3), and the customized solution is administered by constant IV infusion. The clinician must routinely monitor the animal's weight; rectal temperature; and serum sodium, chloride, potassium, phosphorus, and glucose concentrations (in addition to the urine for glucosuria). The feeding solution is adjusted to prevent or correct serum imbalances. PPN is similar but (1) supplies only approximately 50% of caloric needs, (2) has a lower osmolality than TPN solutions so that peripheral IV catheters are sufficient, and (3) is intended to be used for approximately a week with the goal to get a severely ill or emaciated patient "over the hump" before starting enteral nutrition. Regardless of whether TPN or PPN is used, the animal should also receive some feedings orally, if possible, to help prevent intestinal villous atrophy.

# **ANTIEMETICS**

Antiemetics are indicated for symptomatic therapy in many animals with acute vomiting or those in which vomiting is contributing to morbidity (e.g., discomfort or excessive fluid and electrolyte losses). Peripherally acting drugs (Table 30-3) are less effective than centrally acting ones but may suffice in animals with minimal disease. Some of these drugs are given orally, but this is an unreliable route in nauseated animals. Parasympatholytics (e.g., atropine, aminopentamide) have been used extensively. Although they are given parenterally and may have some central activity, they are seldom effective in animals with severe vomiting.

If it is important to halt the vomiting, a centrally acting drug should be administered parenterally. Suppositories are convenient, but their absorption is erratic.

Phenothiazine derivatives (e.g., prochlorperazine [Compazine]) are often effective. They inhibit the chemoreceptor trigger zone and, in higher doses, the medullary vomiting center. Antiemesis is usually achieved at doses that do not produce marked sedation. However, these drugs may cause vasodilation and can decrease peripheral perfusion in a

1 mg/kg SC q24h or 2 mg/kg PO q24h (dogs only) 3 mg/kg, IM q8h (dogs only)

2-4 mg/kg PO q8h 1-2 mg/kg IV or IM q8-12h

dehydrated animal. Some data suggest that phenothiazines may lower the seizure threshold in animals with epilepsy, but this is uncertain.

Metoclopramide (Reglan) inhibits the chemoreceptor trigger zone and increases gastric tone and peristalsis, both of which inhibit emesis. Rarely, animals show unusual behavior after administration. The drug is excreted in the urine, and severe renal failure makes adverse effects more likely. It rarely worsens vomiting, perhaps because it causes excessive gastric contractions. The liquid form of metoclopramide given orally is often not accepted by cats. Because of its prokinetic activity, the drug is contraindicated in animals with a gastric or duodenal obstruction. Metoclopramide may be more effective in animals with severe vomiting if given intravenously at a dosage of 1 to 2 mg/kg/day by constant rate infusion.

Ondansetron (Zofran) and dolasetron (Anzemet) are serotonin receptor antagonists. Developed for use in people with vomiting resulting from chemotherapy, they are often effective in animals in which vomiting is not controlled with phenothiazines or metoclopramide (e.g., severe canine parvoviral enteritis). Granisetron (Kytril) has been used when an oral medication is required, but its efficacy is uncertain.

Maropitant (Cerenia) is a neurokinin-1 receptor antagonist that has recently been approved for use in dogs. Preliminary data suggest that this will be a useful drug in clinical practice.

Narcotics, such as fentanyl, oxymorphone, and butorphanol, may cause vomiting initially, but vomiting is usually inhibited once the drug penetrates to the medullary vomiting center. Trimethobenzamide (Tigan) and antihistamines are effective in some animals but generally are unreliable antiemetics in dogs and cats.

# ANTACID DRUGS

Antacid drugs (Table 30-4) are indicated when appropriate to lessen gastric acidity (e.g., ulcer disease; acid hypersecretion resulting from renal failure, mast cell tumor, or gastrinoma). Although they are not antiemetics, they apparently may have an "antidyspepsic" effect due to diminishing gastric hyperacidity.

Antacids, which titrate the gastric acidity, are over-thecounter preparations that are typically of limited efficacy because of the way they are administered. Compounds containing aluminum or magnesium tend to be more effective and do not cause the gastric acid rebound that sometimes occurs in response to calcium-containing antacids. Antacids should be administered orally every 4 to 6 hours

PO, Orally; SC, subcutaneously; IM, intramuscularly.

<sup>\*</sup> Dosages are for both dogs and cats unless otherwise specified.

<sup>†</sup>This drug contains salicylate and can be nephrotoxic if combined with other nephrotoxic drugs.

to ensure continued control of gastric acidity; however, this may cause diarrhea, especially in animals receiving magnesium-containing compounds. Hypophosphatemia, although unlikely, is possible after extensive aluminum hydroxide administration. Hypermagnesemia, also unlikely, is possible in dogs and cats with renal failure that are given magnesium-containing compounds. These types of antacids may also interfere with the absorption of some other drugs (e.g., tetracycline, cimetidine).

Histamine<sub>2</sub> (H<sub>2</sub>) receptor antagonists are indicated when controlling gastric acidity is important. They act by preventing histamine from stimulating the gastric parietal cell. Cimetidine (Tagamet) is effective but should be given three or four times per day to achieve best results; it inhibits hepatic cytochrome P-450 enzymes, thereby slowing the metabolism of some drugs. Famotidine (Pepcid) and nizatidine (Axid) are as or more effective than cimetidine when administered one or two times per day and do not affect hepatic enzyme activity as much as cimetidine does. It is not clear that ranitidine is effective in dogs. The H<sub>2</sub> receptor

antagonists are now available as over-the-counter preparations. The main indication for these drugs is the treatment of gastric and duodenal ulcers. Some clinicians use them prophylactically in an attempt to prevent ulceration associated with the use of some steroids and some nonsteroidal antiinflammatory drugs (NSAIDs), but they are most effective in treating existing ulcers after NSAID or steroid therapy has ceased. They are effective in lessening ulceration associated with submaximal exertion. Nizatidine and ranitidine have gastric prokinetic activity. Very rarely, these drugs may cause bone marrow suppression, central nervous system problems, or diarrhea. Parenteral administration, especially the rapid IV injection of ranitidine, may cause nausea, vomiting, or bradycardia. There is concern that severely ill or stressed animals may require larger than currently recommended doses in order to suppress gastric acid secretion; this is being investigated.

Proton pump inhibitors (i.e., Omeprazole [Prilosec], lansoprazole [Prevacid], and pantoprazole [Protonix]) block the final common pathway of gastric acid secretion. This is the most effective class of drugs for decreasing gastric acid secretion, but maximum suppression of acid secretion takes between 2 and 5 days when administered orally. Omeprazole is a noncompetitive inhibitor primarily used in animals with severe gastroesophageal reflux or gastrinomas (diseases in which H<sub>2</sub> receptor-antagonists are often inadequate). It is uncertain whether most animals with gastric ulcers benefit from the enhanced blockade of gastric acid secretion that this drug provides, as compared with H<sub>2</sub> receptor-antagonist therapy.

## INTESTINAL PROTECTANTS

Intestinal protectants (Table 30-5) include drugs and inert adsorbents such as kaolin, pectin and barium sulfate contrast media. Many people believe that inert adsorbents hasten clinical relief in animals with minor inflammation, possibly because they coat the mucosa or adsorb toxins. They probably make fecal consistency more normal simply by increasing fecal particulate matter. Inert adsorbents do not have a proven efficacy in the treatment of gastritis or enteritis. It is inappropriate to rely on these drugs alone in very sick animals.

Sucralfate (Carafate) is principally indicated for animals with gastroduodenal ulceration or erosion but might also be useful for those with esophagitis (especially if administered as a slurry). It does not appear to effectively prevent NSAID-induced ulceration but may help prevent stress ulceration. Sucralfate is a nonabsorbable, sulfated sucrose complex that protects denuded mucosa by adhering tightly to it. It also inhibits peptic activity and may alter prostaglandin synthesis and the actions of endogenous sulfhydryl compounds. The dose is extrapolated from humans on the basis of the animal's weight. Although no supportive data are available for dogs and cats, sucralfate and H<sub>2</sub> receptor-antagonists are often used concurrently in animals with severe gastrointes-

PO, Orally; SC, subcutaneously; IM, intramuscularly; IV, intravenously.

<sup>\*</sup> Dosages are for both dags and cats unless otherwise specified. † Dosages based upon anecdotal reports. These drugs have not been used extensively, and their saftey and efficacy in dogs are not established.

<sup>§</sup> Anecdotal reports suggest that higher doses may be necessary in severely ill or severely stressed patients.

# TABLE 30-5

# Selected Gastrointestinal Protectants and Cytoprotective Agents

DRUG	DOSAGE*	COMMENT
Sucralfate (Carafate)	0.5-1 g (dogs) or 0.25 g (cats) PO q6-8h, depending on animal's size	Potentially constipating, absorbs some other orally administered drugs, primarily used to treat existing ulcers
Misoprostol (Cytotec)	2-5 μg/kg PO q8h (dogs)	May cause diarrhea/abdominal cramps, primarily used to prevent ulcers, not for use in pregnant animals

<sup>\*</sup> Dosages are for both dogs and cats unless otherwise specified.

tinal tract ulceration or erosion. However, because sucralfate may adsorb other drugs, other orally administered drugs should probably be given 1 to 2 hours before or after sucralfate administration. An acidic pH promotes optimal activity, and there is typically sufficient acid remaining after  $H_2$  receptor—antagonist therapy for sucralfate to be effective. There are no absolute contraindications to the use of sucralfate. The biggest disadvantage is that it must be given orally, and many animals that need it are vomiting. Sucralfate can cause constipation.

Misoprostol (Cytotec) is a prostaglandin E<sub>1</sub> analog used to treat ulcers but especially to help prevent NSAID-induced gastroduodenal ulceration. The drug is primarily used in dogs that require NSAIDs but in which NSAIDs cause anorexia or vomiting. Use of NSAIDs that have a higher risk of causing gastrointestinal tract problems (e.g., piroxicam) might also be an indication. Misoprostol does not appear to be as effective in preventing NSAID-induced ulcers in dogs as it is in people. The major adverse effects of misoprostol seem to be abdominal cramping and diarrhea, which usually disappear after 2 to 3 days of therapy. Pregnancy may be a contraindication. There is evidence that misoprostol may have immunosuppressant properties, especially in combination with other drugs.

## DIGESTIVE ENZYME SUPPLEMENTATION

Pancreatic enzyme supplementation is indicated to treat exocrine pancreatic insufficiency; however, it is often used empirically without justification in animals with diarrhea. There are many products that vary greatly in their potency. Although pills may work, powdered preparations tend to be more effective; enteric-coated pills are particularly ineffective. Viokase-V (A.H. Robins Co.) and Pancreazyme (Daniels Pharmaceuticals) seem to be particularly efficacious. The powder should be mixed with the food (approximately 1 to 2 teaspoons per meal), but allowing the mixture to "incubate" before feeding has not been found beneficial. Fat is the main nutrient that must be digested in animals with exocrine pancreatic insufficiency, and feeding them a low-fat diet may ameliorate diarrhea. Antacid or antibiotic therapy (or both) may occasionally help prevent gastric acidity or small intes-

PO. Orally

tinal bacteria from rendering the enzyme supplementation ineffective. Occasionally, a stomatitis or diarrhea develops in dogs receiving large amounts of enzyme supplementation.

#### **MOTILITY MODIFIERS**

Drugs that prolong the intestinal transit time are principally used to symptomatically treat diarrhea. Although infrequently needed, they are indicated if the diarrhea causes excessive fluid or electrolyte losses or owners demand control of the diarrhea at home. Opiates (Table 30-6) increase resistance to flow by augmenting segmental contraction. They tend to be more effective than parasympatholytics, which paralyze motility in the intestines (i.e., create ileus). Both

<sup>\*</sup> Dosages are for both dogs and cats unless otherwise specified. †This drug contains salicylate and can be nephrotoxic if combined with other nephrotoxic drugs.

classes of drugs have antisecretory effects. Because cats do not tolerate narcotics as well as dogs, opiates should not be used in this species, although loperamide may be used carefully.

Loperamide (Imodium) is available as an over-thecounter drug. Use of loperamide theoretically increases the risk for bacterial proliferation in the intestinal lumen, thus potentially initiating or perpetuating disease; however, this is very rare in clinical practice. An overdose can cause narcotic intoxication (i.e., collapse, vomiting, ataxia, hypersalivation), which requires treatment with narcotic antagonists.

Diphenoxylate (Lomotil) is similar to loperamide but tends to be somewhat less effective. It has more potential for toxicity than loperamide. Rarely, a dog responds to it but not to loperamide. This drug should not be used in cats.

Drugs that shorten the transit time (prokinetic drugs) empty the stomach or increase intestinal peristalsis or both. Metoclopramide is a prokinetic drug that is effective only in the stomach and the proximal duodenum. However, it can be administered parenterally. Adverse effects are mentioned under the section on antiemetics. Cisapride stimulates normal motility from the lower esophageal sphincter to the anus. It is usually effective unless the tissue has been irreparably damaged (e.g., megacolon in cats). Primarily used for the treatment of constipation, it may also be used for the management of gastroparesis (in which it is usually more effective than metoclopramide) and small intestinal ileus. It has rarely been reported to be beneficial in dogs with megaesophagus. Cisapride is no longer available from human pharmacies but is generally available from veterinary pharmacies. It is available only as an oral preparation. It has few significant adverse effects, although intoxication with large doses may cause diarrhea, muscular tremors, ataxia, fever, aggression, and other central nervous system signs. Erythromycin stimulates motilin receptors and enhances gastric motility at doses less than required for antibacterial activity (i.e., 2 mg/kg). It may also increase intestinal motility. Nizatidine and ranitidine are H2 receptor antagonists that also have gastric prokinetic effects at routinely used doses. Bethanechol (Urecholine) is an acetylcholine analog that stimulates intestinal motility and secretion. It produces strong contractions that can cause pain or injure the animal; hence, it is infrequently used, except for increasing urinary bladder contractions. Obstruction of an outflow area can be a contraindication to the use of prokinetic drugs because vigorous contractions against such a lesion may cause pain or perforation. Obstruction of the urinary outflow tract is also a contraindication to the use of bethanechol. Tegaserod (Zelnorm) has prokinetic activity in the canine colon (0.05 to 0.1 mg/kg, q12h), but there is too little information regarding its effectiveness in clinical disease to make recommendations about its use.

Pyridostigmine (Mestinon) inhibits acetylcholinesterase and is used to treat myasthenia gravis (see Chapter 71). It is used for the treatment of acquired megaesophagus associated with the formation of antibodies to acetylcholine recep-

tors. It must be used cautiously because overdose may cause toxicity accompanied by signs of parasympathetic overload (e.g., vomiting, miosis, diarrhea). Azathioprine (with or without steroids) may be a better long-term treatment for myasthenia gravis than pyridostigmine.

# ANTIINFLAMMATORY AND ANTISECRETORY DRUGS

Intestinal antiinflammatory or antisecretory drugs (or both) are indicated for lessening the fluid losses resulting from diarrhea or for controlling intestinal inflammation that is unresponsive to dietary or antibacterial therapy.

Bismuth subsalicylate (Pepto-Bismol, Kaopectate) is an over-the-counter antidiarrheal agent that is effective in many dogs with acute enteritis (see Table 30-6), probably because of the antiprostaglandin activity of the salicylate moiety. The main disadvantages are that the salicylate is absorbed (warranting its cautious use in cats or in dogs receiving other nephrotoxic drugs), it turns stools black (which mimics melena), and it must be administered orally (many animals dislike its taste). Bismuth is bactericidal for certain organisms (e.g., *Helicobacter* spp.).

Octreotide (Sandostatin) is a synthetic analog of somatostatin that inhibits alimentary tract motility and the secretion of gastrointestinal hormones and fluids. It has had limited use in dogs and cats but might be helpful in a few animals with intractable diarrhea or pancreatitis.

Salicylazosulfapyridine (sulfasalazine [Azulfidine]) is indicated for animals with colonic inflammation. This drug is generally not beneficial in animals with small intestinal problems. It is a combination of sulfapyridine and 5-aminosalicylic acid. Colonic bacteria split the molecule, and the 5-aminosalicylic acid (probably the active moiety) is subsequently deposited on diseased colonic mucosa. Dogs generally receive 50 to 60 mg/kg, divided into three doses daily, but not to exceed 3 g daily. Sulfasalazine may be effective at lower-than-expected doses if used in combination with glucocorticoids. Empirically, 15 mg/kg/day, sometimes divided into twice-daily doses, is often tolerated by cats, but they must be closely observed for the development of salicylate intoxication (i.e., lethargy, anorexia, vomiting, hyperthermia, tachypnea). Some cats that vomit or become anorectic may tolerate the medication if it is given in entericcoated tablets. Many dogs with colitis respond to therapy in 3 to 5 days. However, the drug should be given for 2 weeks before deciding that it is ineffective. If signs of colitis resolve, the dose of the drug should be gradually reduced. If the animal cannot be weaned off the drug entirely, the lowest effective dose should be used and the animal monitored regularly for the development of drug-induced adverse effects (especially those resulting from the sulfa drug). Sulfasalazine may cause transient or permanent keratoconjunctivitis sicca. Other possible complications include cutaneous vasculitis, arthritis, bone marrow suppression, diarrhea, and any other problem associated with sulfa drugs or NSAIDs.

Olsalazine and mesalamine contain or are metabolized to 5-aminosalicylic acid but do not have the sulfa, which is responsible for most of sulfasalazine's adverse effects. In people they are as effective as sulfasalazine but safer. Olsalazine and mesalamine have been used effectively in dogs. They are given in a dose generally about one half that of sulfasalazine. Keratoconjunctivitis sicca has also been found in dogs receiving mesalamine.

Corticosteroids are specifically indicated in animals with chronic alimentary tract inflammation (e.g., moderate to marked inflammatory bowel diseases) that is not responsive to well-designed elimination diets. In cats prednisolone appears to have better activity than prednisone. Relatively high doses (i.e., prednisolone, 2.2 mg/kg/day) are often used initially, and the dose is tapered to find the lowest effective dose. Dexamethasone is sometimes effective when prednisolone is not, but dexamethasone has more adverse effects than prednisolone. If PO administration is a problem in a cat, long-lasting steroid injections (e.g., methylprednisolone acetate) may be tried.

Methyprednisolone appears to be more effective than prednisolone, requiring only 80% of the dose used for prednisolone. Budesonide (Entocort) is a steroid that is not more effective than prednisolone but is largely eliminated by first pass metabolism in the liver, which decreases its systemic effects. The response may be rapid or take weeks.

Corticosteroids are often beneficial in cats with inflammatory bowel disease, but they may worsen intestinal disease in some dogs and cats. Iatrogenic Cushing's syndrome is more of a problem in dogs but can occur in cats that are grossly overdosed. It is important to have a histologically based diagnosis before using high-dose prednisolone therapy because some diseases that mimic steroid-responsive lymphocytic colitis (e.g., histoplasmosis) are absolute contraindications to corticosteroid therapy. Although more common in the southeastern United States and the Ohio River Valley, histoplasmosis has been found in unexpected states.

Retention enemas of corticosteroids or 5-aminosalicylic acid are sometimes indicated in animals with severe distal colitis. The dose is estimated from the human dose. These enemas place large doses of an antiinflammatory agent directly on the affected area while minimizing systemic effects. Although effective in controlling the clinical signs, their administration is unpleasant for both clients and animals. Further, the active ingredient may be absorbed if there is substantial inflammation and increased mucosal permeability (i.e., animals receiving corticosteroid enemas can become polyuric and polydipsic). Therapeutic retention enemas are typically used until the clinical signs are controlled and other therapy (e.g., sulfasalazine, diet) becomes effective. The contraindications to their use are the same as those to the systemic administration of the active ingredient of the enema.

Immunosuppressive therapy (e.g., azathioprine, chlorambucil, cyclosporine) is indicated in animals with severe inflammatory bowel disease that is unresponsive to corticosteroid and dietary therapy. It is also used in animals with severe disease in which it is in the animal's best interest to use aggressive therapy initially. These drugs should be used only if the diagnosis has been confirmed histopathologically. Immunosuppressive therapy can be more efficacious than corticosteroid therapy alone and allows corticosteroids to be given at lower doses and for shorter periods, thereby decreasing their adverse effects. However, the possibility of adverse effects from these drugs usually limits their use to animals with severe disease. The reader is referred to Chapter 103 for additional information on immunosuppressive therapy.

Azathioprine (Imuran) is commonly used in dogs (50 mg/m² daily or every other day) with severe alimentary tract inflammation. Azathioprine should not be used in cats because of the risk for myelotoxicity. For smaller dogs a 50-mg azathioprine tablet is typically crushed and suspended in a liquid (e.g., 15 ml of a vitamin supplement) to allow more accurate dosing. The suspension must be mixed well before each dosing. It may take 2 to 5 weeks before the beneficial effects of this drug are seen. Side effects in dogs may include hepatic disease, pancreatitis, and bone marrow suppression.

Chlorambucil is an alkylating agent that is used for the same reasons as azathioprine. Chlorambucil, however, appears to have fewer adverse effects than azathioprine. A reasonable starting dose in cats is 1 mg twice weekly for cats weighing less than 7 lb (3.5 kg) and 2 mg twice weekly for cats weighing more than that. Beneficial effects may not be seen for 4 to 5 weeks. If a response is seen, the dose should then be decreased very slowly over the next 2 to 3 months. The animal should be monitored for myelosuppression. Stronger alkylating agents, such as cyclophosphamide, are seldom used for the management of nonneoplastic gastrointestinal tract disease.

Cyclosporine (Atopica) is a potent immunosuppressive drug that is sometimes used in dogs with inflammatory bowel disease, lymphangiectasia, and perianal fistulas. The dose is 3 to 5 mg/kg q12h when given orally, but erratic bioavailability requires therapeutic drug monitoring and subsequent adjusting of the dose. There is considerable variation in the bioavailability of different preparations of cyclosporine. It may be administered intravenously in vomiting patients, but then the initial dose should probably be decreased by 50%. Because of its considerable expense, it is sometimes administered with low doses of ketoconazole (3 to 5 mg/kg q12h), which inhibits metabolism of cyclosporine and in turn allows the use of lower doses at less expense to the client.

# **ANTIBACTERIAL DRUGS**

In dogs and cats with gastrointestinal problems, antibiotics are primarily indicated if aspiration pneumonia, fever, a leukogram suggestive of sepsis, severe neutropenia, antibiotic-responsive enteropathy, clostridial colitis, symptomatic Helicobacter gastritis, or perhaps hematemesis or melena is found or suspected. Animals with an acute abdomen may reasonably be treated with antibiotics while the nature of the disease is being defined. Acute colitis is a reasonable indication for amoxicillin (22 mg/kg q12h) because clostridial colitis is reasonably common. However, most animals with acute enteritis or gastritis of unknown cause do not benefit from antibiotic therapy. In general, the routine use of antimicrobials in animals with alimentary tract disorders is not recommended, unless the animal is at high risk for infection or a specific disorder is being treated.

Nonabsorbable aminoglycosides (e.g., neomycin) are often used to "sterilize" the intestines. However, they do not kill anaerobic bacteria, which are the predominant type found there. Further, there are a plethora of viral and dietary causes of acute enteritis that are not responsive to antibiotics. Thus aminoglycosides given orally are not indicated unless a specific infection (e.g., campylobacteriosis) is being considered.

Broad-spectrum antibiotics effective against aerobes and anaerobes may be used for the treatment of antibioticresponsive enteropathy (ARE). Metronidazole (10 to 15 mg/ kg q24h) may also be used for this purpose (see later discussion) but has not been as successful in this author's experience. Tylosin (20 to 40 mg/kg q12h) is commonly used for this purpose. Tetracycline (22 mg/kg q12h) has also been used, and patients with severe disease believed to have ARE may be treated with combinations (e.g., metronidazole and enrofloxacin [7 mg/kg .q24h]). Inappropriate antibiotic therapy may hypothetically eliminate enough resident bacteria that overgrowth of pathogenic bacteria in the colon occurs. However, this is rarely a clinical problem in dogs and cats. The clinician should treat the patient for at least 2 to 3 weeks before deciding that therapy for ARE has been unsuccessful.

Pets occasionally have enteritis caused by a specific bacterium. However, even this is not necessarily an indication for antibiotics. Clinical signs resulting from some bacterial enteritides (e.g., salmonellosis, enterohemorrhagic *Escherichia coli*) generally do not resolve more quickly when the animal is treated with antibiotics, even those to which the bacteria are sensitive.

Dogs and cats with viral enteritis but without obvious systemic sepsis may reasonably be treated with antibiotics if secondary sepsis is likely to occur (e.g., those with neutropenia or severe hemorrhagic diarrhea). First-generation cephalosporins (e.g., cefazolin) are often effective for such use.

If systemic or abdominal sepsis is suspected to have originated from the alimentary tract (e.g., septicemia caused by parvoviral enteritis, perforated intestine), broad-spectrum antimicrobial therapy is indicated. Antibiotics with a good aerobic gram-positive and anaerobic spectrum of action (e.g., ticarcillin plus clavulinic acid [Timentin], 50 mg/kg given intravenously three to four times daily, or clindamycin, 11 mg/kg given intravenously three times daily) combined with antibiotics with excellent activity against most aerobic

bacteria (e.g., amikacin, 25 mg/kg given intravenously once daily or enrofloxacin, 15 mg/kg given intravenously once daily) are often effective. To improve the anaerobic spectrum, especially if a cephalosporin is used instead of ampicillin, the clinician may include metronidazole (10 mg/kg given intravenously two or three times daily). Alternatively, a second-generation cephalosporin (e.g., cefoxitin, 30 mg/kg given intravenously three or four times daily) may be used. In general, it takes at least 48 to 72 hours before the clinician can tell whether the therapy will be effective.

Helicobacter gastritis may be treated with various combinations of drugs. Currently, the combination of an antacid (i.e., famotidine or omeprazole; see Table 30-4) and a macrolide (i.e., erythromycin or azithromycin; see pp. 483–485) or amoxicillin seems to be very effective. Adding metronidazole and/or bismuth subsalicylate may enhance efficacy. However, some patients seem to respond to erythromycin or amoxicillin as a sole agent. If high doses of erythromycin (22 mg/kg given twice daily) cause vomiting, the dose may be lowered to 10 to 15 mg/kg given twice daily. A 10- to 14-day course of treatment appears to be adequate for most animals, although recurrence of infection is possible.

Metronidazole is a "miscellaneous" drug that is commonly used in animals with inflammatory bowel disease. It has antimicrobial activity against anaerobic bacteria (which predominate in the gastrointestinal tract) and protozoa (e.g., Giardia). It has been suggested to have some effect on the immune system, as shown by its apparent beneficial effects in people with Crohn's disease. The usefulness of metronidazole in dogs and cats with inflammatory bowel disease (10 to 15 mg/kg given twice daily) is suspected but unproved. Adverse effects are uncommon but may include salivation (because of its taste), vomiting, central nervous system abnormalities (e.g., central vestibular signs), and perhaps neutropenia. These adverse effects usually resolve after withdrawing the drug. Cats sometimes accept oral suspensions better than the 250-mg tablets, which must be cut and have an unpleasant taste. Some cats diagnosed with inflammatory bowel disease respond to metronidazole better than they do to corticosteroids. Occasionally, dogs with colitis do likewise.

### PROBIOTICS/PREBIOTICS

The administration of live bacteria or yeast in the food with the intent to produce a beneficial effect is called *probiotic therapy*. The administration of a specific dietary substance to specifically increase or decrease the numbers of specific bacteria is called *prebiotic therapy*. The concurrent use of probiotics and prebiotics is called *symbiotic therapy*. Although there is good evidence that these therapies are beneficial for specific conditions in people, there is currently no published work showing a clear benefit in clinically ill dogs or cats. However, this may change with time.

Lactobacillus, Bifidobacterium, and Enterococcus are the bacteria typically administered to dogs. These bacteria are

believed to stimulate Toll-like receptors in the bowel and thereby benefit the patient. The beneficial effect seems to last only as long as the bacteria are being administered. There is no evidence that these bacteria become permanently established in the gastrointestinal microflora during administration. Not all probiotics sold in drug or grocery stores contain what the label states, which may be at least partially responsible for their failure to have demonstrated efficacy. In general, large numbers of bacteria appear to be necessary, which explains why feeding yogurt (which contains relatively modest numbers of *Lactobacilli*) is ineffective. At the time of this writing, there are two products marketed specifically for veterinary use (Fortiflora, Purina Co) that contains *Enterococcus faecium* and Proviable (Nutramax) that contains a mixture of several bacteria.

# **ANTHELMINTIC DRUGS**

Anthelmintics are frequently prescribed for dogs and cats with alimentary tract disease, even if parasitism is not the primary problem. It is often reasonable to use these drugs empirically for the treatment of suspected parasitic infections in animals with acute or chronic diarrhea. Selected anthelmintics are listed in Table 30-7.

# **ENEMAS, LAXATIVES, AND CATHARTICS**

Enemas are classified as either cleansing or retention.

Retention enemas are given so that the material administered stays in the colon until it exerts its desired effects (e.g., antiinflammatory retention enemas are used in animals with inflammatory bowel disease, water in obstipated animals). Obstipated animals may require frequent administrations of modest volumes of water (e.g., 20 to 200 ml, depending on the animal's size) so that the water stays in the colon and gradually softens the feces. The clinician should avoid overdistending the colon or administering drugs that may be absorbed and produce undesirable effects. Suspected or pending colonic rupture is a contraindication to the use of enemas, but this outcome is difficult to predict. Animals that have undergone neurosurgery (e.g., those that have had a hemilaminectomy) and are receiving corticosteroids (e.g., dexamethasone) may be at increased risk for colonic perforation. Animals with colonic tumors or that have recently undergone colonic surgery or biopsy should not receive enemas either, unless there is an overriding reason.

Cleansing enemas are designed to remove fecal material. They involve the repeated administration of relatively large volumes of warm water. In dogs the water is administered by gravity flow from a bucket or bag held above the animal. The tube is gently advanced as far as it will easily go into the colon. Between 50 and 100 ml is tolerated by most small dogs, 200 to 500 ml by medium-size dogs, and 1 to 2 L by large dogs. Care should be taken to avoid overdistending or

perforating the colon. Enemas are usually administered to cats with a soft canine male urinary catheter and a 50-ml syringe. If fluid is administered too quickly, however, the cat will usually vomit. A suspected or pending colonic perforation is also a contraindication to a cleansing enema.

Hypertonic enemas are potentially dangerous and should be used cautiously (if at all) because they can cause massive, fatal fluid and electrolyte shifts (i.e., hyperphosphatemia, hypocalcemia, hypokalemia, hyperkalemia). This is especially true for cats, small dogs, and any animal that cannot quickly evacuate the enema because of obstipation.

Cathartics and laxatives (Table 30-8) should be used only to augment defecation in animals that are not obstructed. They are not routinely indicated in small animals, except perhaps as part of lower bowel cleansing before contrastenhanced abdominal radiography or endoscopy.

Irritative laxatives (e.g., bisacodyl) stimulate defecation rather than soften feces. They are often used before colonoscopic procedures and in animals that are reluctant to defecate because of an altered environment. They are probably not appropriate for long-term use because of the dependence and colonic problems noted in people who have used them inappropriately. A glycerin suppository or a lubricated match stick is often an effective substitute for an irritative laxative. These objects are carefully placed in the rectum to stimulate defecation.

Bulk and osmotic laxatives include a variety of preparations: various fibers (especially the soluble ones); magnesium sulfate; lactulose; and, in milk-intolerant animals, ice cream or milk. They promote the fecal retention of water and are indicated in animals that have overly hard stools not caused by the ingestion of foreign objects. These laxatives are more appropriate for long-term use than the irritative cathartics are. Larger doses may be needed in cats because they retain fluids more effectively than dogs do.

Fiber is a bulking agent that is incorporated into the food and can be used indefinitely. Commercial diets relatively high in fiber may be used, or existing diets may be supplemented with fiber (see pp. 400–401). It is important to supply adequate amounts of water so that the additional fiber does not cause the formation of harder-than-normal stools. Too much fiber may cause excessive stool or inappetence resulting from decreased palatability (a danger for fat cats at risk for hepatic lipidosis). Fiber should not be given to animals with a partial or complete alimentary tract obstruction because impaction may occur.

Lactulose (Cephulac) was designed to control signs of hepatic encephalopathy, but it is also a very effective osmotic laxative. It is a disaccharide that is split by colonic bacteria into unabsorbed particles. Lactulose is particularly useful for animals that refuse to eat high-fiber diets. The dose necessary to soften feces must be determined in each animal, but 0.5 or 5 ml may be given two or three times daily to small and large dogs, respectively. Cats often need higher dosages (e.g., 5 ml three times daily). If gross overdosing occurs, so much water can be lost that hypernatremic dehydration ensues. There are no obvious contraindications to the use of lactulose.

DRUG	DOSAGE* (PO)	USE	COMMENTS
Albendazole (Valbazen)	25 mg/kg q12h for 3 days (dogs only) 25 mg/kg q12h for 5 days (cats only)	G	May cause leukopenia in some animals. Do not use in early pregnancy. Not approved for use in dogs.
Fenbendazole (Panacur)	50 mg/kg for 3-5 days	H/R/W/G	Not approved for cats but often used for 3-5 days in cats to eliminate Giardia. Give with food.
Furazolidone Metronidazole (Flagyl)	4.4 mg/kg q12h for 5 days 25-50 mg/kg for 5-17 days (dogs only) 25-50 mg/kg for 5 days (cats only)	G G	— Rarely see neurologic signs.
Ronidazole	30-50 mg/kg q12h for 14 days (cats only)		For <i>Tritrichomonas</i> infections in cats; drug is not approved for use in animals. Rarely causes neurologic signs.
Pyrantel (Nemex)	5 mg/kg (dogs only) 20 mg/kg, once only (cats only)	H/R/P	Give after meal
Pyrantel/febantel/ praziquantel (Drontal Plus)	1 tablet/10 kg	T/H/R/W	
Imidocloprid/moxidectin (Advantage multi)	Topical—Follow manufacturers' recommendations	H/R/W	
lvermectin	200 μg/kg (dogs only)	H/R/P	Do not use in Collies, Shelties, Border Collies, or Australian Shepherds. Use with caution in Old English Sheepdogs. Only approved for use as heartworm preventive.  Safe to use in dogs with <i>D immitis</i> microfilaremia. Treats <i>Strongyloides</i> .  Generally should use only if other drugs not appropriate.
Milbemycin (Interceptor)	0.5 mg/kg, monthly	H/R/W	Not approved for use in cats. Not safe to use in dogs with <i>D. immitis</i> microfilaremia.
Praziquantel (Droncit)	5 mg/kg for dogs >6.8 kg	Т	10 mg/kg for juvenile Echinococcus
	7.5 mg/kg for dogs <6.8 kg 6.3 mg/kg for cats <1.8 kg 5 mg/kg for cats >1.8 kg For <i>Heterobilharzia</i> , 20 mg/kg SC q8h for 1 day (dog only)		spp.
Episprantel (Cestex)	5.5 mg/kg for dogs 2.75 mg/kg for cats	T	_
Selamectin (Revolution) Sulfadimethoxine (Albon)	6 mg/kg topical for cats 50 mg/kg on day 1, then 27.5 mg/kg q12h for 9 days	H/R C	Not approved for use in dogs.  May cause dry eyes, arthritis,  cytopenia, hepatic disease.
Trimethoprim-sulfadiazine (Tribrissen)	30 mg/kg for 10 days	С	May cause dry eyes, arthritis, cytopenia, hepatic disease.

PO, orally; G, Giardia; H, hookworms; R, roundworms; W, whipworms; P, Physaloptera; T, tapeworms; C, coccidia. \*Dosages are for both dogs and cats unless otherwise specified.

# Selected Laxatives, Cathartics, Stool-Softening Agents, and Bulking Agents

DOSAGE (PO)	COMMENTS
5 mg (small dogs and cats) 10-15 mg (larger dogs)	Do not break tablets
1-3 tbsp/454 g of food	
I-3 tbsp/day (cats only)	Principally for cats
10-200 mg q8-12h (dogs only) 10-25 mg q12-24h (cats only)	Be sure animal is not dehydrated when treating
1 ml/5 kg q8-12h, then adjust dose as needed (dogs only)	Can cause severe osmotic diarrhea
5 ml q8h, then adjust dose as needed	
1-2 tsp/454 g of food	Be sure animal has enough water, or constipation may develop
	5 mg (small dogs and cats) 10-15 mg (larger dogs) 1-3 tbsp/454 g of food 1-3 tbsp/day (cats only) 10-200 mg q8-12h (dogs only) 10-25 mg q12-24h (cats only) 1 ml/5 kg q8-12h, then adjust dose as needed (dogs only) 5 ml q8h, then adjust dose as needed (cats only)

# MASSES, PROLIFERATIONS, AND INFLAMMATION OF THE OROPHARYNX

# **SIALOCELE**

# **Etiology**

Sialoceles are accumulations of saliva in subcutaneous tissues caused by salivary duct obstruction and/or rupture and subsequent leakage of secretions into subcutaneous tissues. Most cases are probably traumatic, but some are idiopathic.

#### **Clinical Features**

A large, usually painless swelling is found under the jaw or tongue or occasionally in the pharynx. Oral cavity sialoceles may cause dysphagia, whereas those located in the pharynx often produce gagging or dyspnea. If traumatized, sialoceles may bleed or cause anorexia due to discomfort.

# Diagnosis

Aspiration with a large-bore needle reveals thick fluid with some neutrophils. The fluid usually resembles mucus, strongly suggesting its salivary gland origin. Contrast radiographic procedures (contrast sialograms) sometimes define which gland is involved.

#### **Treatment**

The mass is opened and drained, and the salivary gland responsible for the secretions must be excised.

## **Prognosis**

The prognosis is excellent if the correct gland is removed.

# SIALOADENITIS/SIALOADENOSIS/ SALIVARY GLAND NECROSIS

#### Etiology

The etiology is unknown, but the condition apparently has occurred as an idiopathic event as well as secondary to vomiting/regurgitation.

#### **Clinical Features**

The condition may cause a painless enlargement of one or more salivary glands (usually the submandibular). If there is substantial inflammation, animals may be dysphagic. A syndrome has been reported in which noninflammatory swelling is associated with vomiting that is responsive to phenobarbital therapy. This syndrome has no established cause and effect.

## **Diagnosis**

Biopsy and cytology or histopathology confirm that the mass is salivary tissue and determine whether inflammation or necrosis is present.

#### **Treatment**

If there is substantial inflammation and pain, surgical removal seems most efficacious. If the patient is vomiting, a search should be made for an underlying cause. If a cause is found, it should be treated and the size of the salivary glands monitored. If no other cause for vomiting can be found, phenobarbital may be administered at anticonvulsant doses (see Chapter 67).

# **Prognosis**

The prognosis is usually excellent.

# NEOPLASMS OF THE ORAL CAVITY IN DOGS

### Etiology

Most soft tissue masses of the oral cavity are neoplasms, and most of these are malignant (i.e., melanoma, squamous cell carcinoma, fibrosarcoma). However, acanthomatous ameloblastomas (previously called *epulides*), fibromatous epulides

(classically in Boxers), oral papillomatosis, and eosinophilic granulomas (e.g., in Siberian Huskies and Cavalier King Charles Spaniels) also occur.

#### **Clinical Features**

The most common signs of tumors of the oral cavity are halitosis, dysphagia, bleeding, or a growth protruding from the mouth. Papillomatosis and fibromatous periodontal hyperplasia are benign growths that may cause discomfort when eating and occasionally cause bleeding, mild halitosis, or tissue protrusion from the mouth. The biologic behaviors of the different tumors are presented in Table 31-1.

## Diagnosis

A thorough examination of the oral cavity (which may require that the animal be under anesthesia) usually reveals a mass involving the gingiva, although the tonsillar area, hard palate, and tongue can also be affected. Diagnosis requires cytologic or histopathologic analysis, although papillomatosis and melanomas may be strongly suspected on the basis of their

**TABLE 31-1** 

Some Characteristics of Selected Oral Tumors

TUMOR	TYPICAL APPEARANCE/ LOCATION	BIOLOGIC BEHAVIOR	PREFERRED THERAPY
Squamous Cell Carc	inoma		
Gingiva	Fleshy or ulcerated/on rostral gingiva	Malignant, locally invasive	Wide surgical resection on rostral gingiva ± radiation; piroxicam often helpful
Tonsil	Fleshy or ulcerated/on one or rarely both tonsils	Malignant, commonly spreads to regional lymph nodes	None (chemotherapy may be of some benefit); piroxicam may be helpful
Tongue margin (dog)	Ulcerated/on margin of tongue	Malignant, locally invasive	Surgical resection of tongue/radiotherapy; piroxicam may be helpful
Base of tongue (cat)	Ulcerated/at base of tangue	Malignant, locally invasive	None (radiotherapy of tongue and/or chemotherapy may be used palliatively)
Malignant Melanoma	Grey or black; can be smooth, usually fleshy/ on gum, tongue, or palate	Very malignant, early metastases to lungs	None (resection and/or radiation are palliative but rarely curative); carboplatin and radiation might help. A vaccine recently has been released; initial reports are encouraging.
Fibrosarcoma	Pink and fleshy/on palate or gums	Malignant, very invasive locally	Wide surgical resection (chemotherapy and/or radiation may be of some value in selected cases)
Acanthomatous Ameloblastoma (Epulis)	Pink and fleshy/on gum or rostral mandible	Malignant, locally invasive	Surgical resection ± radiation
Fibromatous Epulis	Pink, fleshy, solitary or multiple/on gums	Benign	Nothing or surgical resection
Papillomatosis	Pink or white, cauliflower- like, multiple/seen anywhere	Benign	Nothing or surgical resection
Plasmacytoma	Fleshy or ulcerated growth on gingiva	Malignant, locally invasive Rarely metastasizes	Surgical resection ± radiation

gross appearance. The preferred diagnostic approach in a dog with a mass of the oral cavity is to perform an incisional biopsy and to obtain thoracic and skull radiographs or a computed tomography (CT) scan of the affected area. If malignancy is a diagnostic consideration, thoracic radiographs should be obtained to evaluate for metastases (seldom seen but a very poor prognostic sign if present), and maxillary and mandibular radiographs should be obtained to check for bony involvement. Fine-needle aspiration of regional lymph nodes, even if they appear normal, is indicated to detect metastases. Melanomas may be amelanotic and can cytologically resemble fibrosarcomas, carcinomas, or undifferentiated round cell tumors. Biopsy and subsequent histopathologic analysis may be required for a definitive diagnosis.

# **Treatment/Prognosis**

The preferred therapeutic approach in dogs with confirmed malignant neoplasms of the oral cavity and lack of clinically detectable metastases is wide, aggressive surgical excision of the mass and surrounding tissues (e.g., mandibulectomy, maxillectomy). Enlarged regional lymph nodes should be excised and evaluated histopathologically, even if they are cytologically negative for neoplasia. Early complete excision of gingival or hard palate squamous cell carcinomas, fibrosarcomas, acanthomatous epulides, and (rarely) melanomas may be curative. Acanthomatous epulis and ameloblastomas may respond to radiation therapy alone (complete surgical excision is preferred), and squamous cell carcinomas or fibrosarcomas with residual postoperative disease may benefit from postoperative adjunctive radiation therapy. Lingual squamous cell carcinomas affecting the base of the tongue and tonsillar carcinomas have a very poor prognosis; complete excision or irradiation usually causes severe morbidity. Melanomas metastasize early and have a very guarded prognosis. Chemotherapy is usually not beneficial in dogs with squamous cell carcinoma, acanthomatous epulis, and melanoma, but an oncologist should be consulted about new protocols that may provide some benefit. Piroxicam can benefit some patients with squamous cell carcinoma. Combination chemotherapy may be beneficial in some dogs with fibrosarcoma (see Chapter 77). Radiotherapy plus hyperthermia has been successful in some dogs with oral fibrosarcoma.

Papillomatosis usually resolves spontaneously, although it may be necessary to resect some of the masses if they interfere with eating. Fibromatous epulides may be resected if they cause problems.

# NEOPLASMS OF THE ORAL CAVITY IN CATS

### Etiology

Tumors of the oral cavity are less common in cats than in dogs, but they are usually squamous cell carcinomas, which are diagnosed and treated as described for dogs. Cats are different from dogs in that they also have sublingual squamous cell carcinomas and eosinophilic granulomas (which mimic carcinoma but have a much better prognosis).

#### **Clinical Features**

Dysphagia, halitosis, anorexia, and/or bleeding are common features of these tumors.

## Diagnosis

A large, deep biopsy specimen is needed because it is crucial to differentiate malignant tumors from eosinophilic granulomas. The superficial aspect of many masses of the oral cavity is ulcerated and necrotic as a result of the proliferation of normal oral bacterial flora, making it difficult to interpret this part of the mass.

#### **Treatment**

Surgical excision is desirable. Radiation therapy and/or chemotherapy may benefit cats with incompletely excised squamous cell carcinomas not involving the tongue or tonsil.

## **Prognosis**

In general, the prognosis for cats with squamous cell carcinomas of the tongue or tonsil is guarded to poor (see Chapter 82).

#### FELINE EOSINOPHILIC GRANULOMA

## Etiology

The cause of feline eosinophilic granuloma is unknown.

### **Clinical Features**

Feline eosinophilic granuloma complex includes indolent ulcer, eosinophilic plaque, and linear granuloma; however, it has not been established that these diseases are related. Indolent ulcers are classically found on the lip or oral mucosa of middle-aged cats. Eosinophilic plaque usually occurs on the skin of the medial thighs and abdomen. Linear granuloma is typically found on the posterior aspect of the rear legs of young cats but may also occur on the tongue, palate, and oral mucosa. Severe oral involvement of an eosinophilic ulcer or plaque typically produces dysphagia, halitosis, and/or anorexia. Cats with eosinophilic granulomas of the mouth may have concurrent cutaneous lesions.

## Diagnosis

An ulcerated mass may be found at the base of the tongue or on the hard palate, the glossopalatine arches, or anywhere else in the mouth. A deep biopsy specimen of the mass is necessary for accurate diagnosis. Peripheral eosinophilia is inconsistently present.

#### **Treatment**

High-dose corticosteroid therapy (oral prednisolone, 2.2 to 4.4 mg/kg/day) often controls these lesions. Sometimes cats are best treated with methylprednisolone acetate injections (20 mg every 2 to 3 weeks as needed) instead of oral prednisolone. Although effective, megestrol acetate may cause diabetes mellitus, mammary tumors, and uterine problems and probably should not be used except under extreme

constraints. Chlorambucil might prove useful in resistant cases.

# **Prognosis**

The prognosis is good, but the lesion can recur.

# GINGIVITIS/PERIODONTITIS

# **Etiology**

Bacterial proliferation and toxin production, usually associated with tartar buildup, destroy normal gingival structures and produce inflammation. Immunosuppression caused by feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and/or feline calicivirus may predispose some cats to this disease.

#### **Clinical Features**

Dogs and cats may be affected. Many are asymptomatic, but halitosis, oral discomfort, refusal to eat, dysphagia, drooling, and tooth loss may occur.

# Diagnosis

Visual examination of the gums reveals hyperemia around the tooth margins. Gingival recession may reveal tooth roots. Accurate diagnosis can be made through probing and oral radiographs. The stage of periodontal disease is defined by radiographs.

#### **Treatment**

Supragingival and subgingival tartar should be removed, and the crowns should be polished. Antimicrobial drugs effective against anaerobic bacteria (e.g., amoxicillin, clindamycin, metronidazole; see Drugs Used in Gastrointestinal Disorders table, pp. 481–483) may be used before and after cleaning teeth. Regular brushing of the teeth and/or oral rinsing with a veterinary chlorhexidine solution formulated for that purpose helps to control the problem.

#### **Prognosis**

The prognosis is good with proper therapy.

#### **STOMATITIS**

#### Etiology

There are many causes of canine and feline stomatitis (Box 31-1). The clinician should always consider the possibility of immunosuppression with secondary stomatitis (e.g., FeLV, FIV, diabetes mellitus, hyperadrenocorticism).

# **Clinical Features**

Most dogs and cats with stomatitis have thick, ropey saliva; severe halitosis; and/or anorexia caused by pain. Some animals are febrile and lose weight.

### Diagnosis

A thorough oral examination usually requires that the animal be under anesthesia. Stomatitis is diagnosed by gross obser-

#### Common Causes of Stomatitis

Renal failure

Trauma

Foreign objects

Chewing or ingesting caustic agents

Chewing on electrical cords

Immune-mediated disease

Pemphigus

Lupus

Upper respiratory viruses (feline viral rhinotracheitis, feline calicivirus)

Infection secondary to immunosuppression (feline leukemia virus, feline immunodeficiency virus)

Tooth root abscesses

Severe periodontitis

Osteomyelitis

Thallium intoxication

vation of the lesions, but an underlying cause should be sought. Biopsy is routinely indicated, as are routine clinical pathology data and radiographs of the mandible and maxilla, including the tooth roots.

#### Treatment

Therapy is both symptomatic (to control signs) and specific (i.e., directed at the underlying cause). Thorough teeth cleaning and aggressive antibacterial therapy (i.e., systemic antibiotics effective against aerobes and anaerobes, cleansing oral rinses with antibacterial solutions such as chlorhexidine) often help. In some animals extracting teeth that are associated with the most severely affected areas may help. Bovine lactoferrin has been reported to ameliorate otherwise resistant lesions in cats.

#### **Prognosis**

The prognosis depends on the underlying cause.

# FELINE LYMPHOCYTIC-PLASMACYTIC GINGIVITIS/PHARYNGITIS

#### Etiology

An idiopathic disorder, feline lymphocytic-plasmacytic gingivitis might be caused by feline calicivirus or any stimulus producing sustained gingival inflammation. Cats appear to have an excessive oral inflammatory response that can produce marked gingival proliferation.

#### **Clinical Features**

Anorexia and/or halitosis are the most common signs. Affected cats grossly have reddened gingiva around the teeth and/or posterior pillars of the pharynx. The gingiva may be obviously proliferative in severe cases and bleed easily. Dental neck lesions often accompany the gingivitis. Teeth chattering is also occasionally seen.

# Diagnosis

Biopsy of affected (especially proliferative) gingiva is needed for diagnosis. Histologic evaluation reveals a lymphocyticplasmacytic infiltration. Serum globulin concentrations may be increased.

#### **Treatment**

There is currently no reliable therapy for this disorder. Proper cleaning and polishing of teeth and antibiotic therapy effective against anaerobic bacteria may help. High-dose corticosteroid therapy (prednisolone, 2.2 mg/kg/day) is often useful. In some severe cases, multiple tooth extractions may alleviate the source of the inflammation. However, extraction of the canine teeth should be delayed. Immunosuppressive drugs such as chlorambucil also may be tried in obstinate cases.

## **Prognosis**

The prognosis is guarded; severely affected animals often do not respond well to therapy.

# DYSPHAGIAS JERPENNICHE MERCHICLE

# MASTICATORY MUSCLE MYOSITIS/ ATROPHIC MYOSITIS

## Etiology

Masticatory muscle myositis/atrophic myositis is an idiopathic, immune-mediated disorder that affects the muscles of mastication in dogs. The syndrome has not been reported in cats.

#### **Clinical Features**

In the acute stages the temporalis and masseter muscles may be swollen and painful. However, many dogs are not presented until the muscles are severely atrophied and the mouth cannot be opened.

## Diagnosis

Atrophy of the temporalis and masseter muscles and the inability to open the dog's mouth while it is anesthetized allow the clinician to establish a presumptive diagnosis. Muscle biopsy of the temporalis and masseter muscles provides confirmation. The presence of antibodies to type 2M fibers strongly supports this diagnosis.

#### **Treatment**

High-dose prednisolone therapy (2.2 mg/kg/day) with or without azathioprine (50 mg/m² q24 h) is usually curative. Once control has been achieved, the prednisolone and azathioprine are administered every 48 hours and then the dose of prednisolone is tapered to avoid adverse effects. However, this tapering must be done slowly to prevent recurrence (see the section on immunosuppressive drugs in Chapter 103). If needed, a gastrostomy tube may be used until the animal can eat.

# **Prognosis**

The prognosis is usually good, but continued medication may be needed.

# CRICOPHARYNGEAL ACHALASIA/ DYSFUNCTION

# Etiology

The cause of cricopharyngeal achalasia/dysfunction is unknown, but it is usually congenital. There is an incoordination between the cricopharyngeus muscle and the rest of the swallowing reflex, which produces obstruction at the cricopharyngeal sphincter during swallowing (i.e., the sphincter does not open at the proper time). The problem has a genetic basis in Golden Retrievers.

#### **Clinical Features**

Primarily seen in young dogs, cricopharyngeal achalasia rarely occurs as an acquired disorder. The major sign is regurgitation immediately after or concurrent with swallowing. Some animals become anorexic, and severe weight loss may occur. Clinically, this condition may be indistinguishable from pharyngeal dysfunction.

## Diagnosis

Definitive diagnosis requires fluoroscopy or cinefluoroscopy while the animal is swallowing barium or another contrast media. A young animal that is regurgitating food immediately on swallowing is suggestive of the disorder, but pharyngeal dysphagia with normal cricopharyngeal sphincter function occasionally occurs as an apparently congenital defect and must be differentiated from cricopharyngeal disease.

## **Treatment**

Cricopharyngeal myotomy can be curative. The clinician must be careful not to cause cicatrix at the surgery site. Esophageal function in the cranial esophagus must be evaluated before this surgery is considered (see the next section, on pharyngeal dysphagia).

# **Prognosis**

The prognosis is good if cicatrix does not occur postoperatively.

### PHARYNGEAL DYSPHAGIA

#### Etiology

Pharyngeal dysphagia is primarily an acquired disorder, and neuropathies, myopathies, and junctionopathies (e.g., localized myasthenia gravis) seem to be the main cause. The inability to form a normal bolus of food at the base of the tongue and/or to propel the bolus into the esophagus is often associated with lesions of cranial nerves IX or X. Simultaneous dysfunction of the cranial esophagus may cause food retention just caudal to the cricopharyngeal sphincter.

### **Clinical Features**

Although pharyngeal dysphagia principally is found in older animals, young animals occasionally have transient signs. Pharyngeal dysphagia often clinically mimics cricopharyngeal achalasia; regurgitation is associated with swallowing. Pharyngeal dysphagia sometimes causes more difficulty with swallowing fluids than solids. Aspiration (especially associated with liquids) is common because the proximal esophagus is often flaccid and retains food, predisposing to later reflux into the pharynx.

## Diagnosis

Fluoroscopy or cinefluoroscopy while the animal is swallowing barium is typically required for diagnosis. An experienced radiologist is needed to reliably distinguish pharyngeal dysphagia from cricopharyngeal dysphagia. With the former condition, the animal does not have adequate strength to properly push boluses of food into the esophagus, whereas in the latter the animal has adequate strength but the cricopharyngeal sphincter stays shut or opens at the wrong time during swallowing, thereby preventing normal movement of food from the pharynx to the proximal esophagus. It appears that some cases may be detected by electromyography of laryngeal, pharyngeal, and esophageal muscles.

#### **Treatment**

Although cricopharyngeal myotomy is often curative for animals with cricopharyngeal achalasia, it may be disastrous for animals with pharyngeal dysphagias because it allows food retained in the proximal esophagus to more easily reenter the pharynx and be aspirated. The clinician must either bypass the pharynx (e.g., gastrostomy tube) or resolve the underlying cause (e.g., treat or control myasthenia gravis).

### **Prognosis**

The prognosis is guarded because it is often difficult to find and treat the underlying cause, and the dog or cat is prone to progressive weight loss and recurring aspiration pneumonia.

# ESOPHAGEAL WEAKNESS/ MEGAESOPHAGUS

## CONGENITAL ESOPHAGEAL WEAKNESS

#### Etiology

The cause of congenital esophageal weakness (i.e., congenital megaesophagus) is unknown. There is no evidence of demyelination or neuronal degeneration, and vagal efferent innervation appears to be normal.

#### **Clinical Features**

Affected animals (primarily dogs) are usually presented because of "vomiting" (actually regurgitation) with or without weight loss, coughing, or fever from pneumonia. Occasionally, coughing and other signs of aspiration tracheitis and/or pneumonia may be the only signs reported by the owner.

## Diagnosis

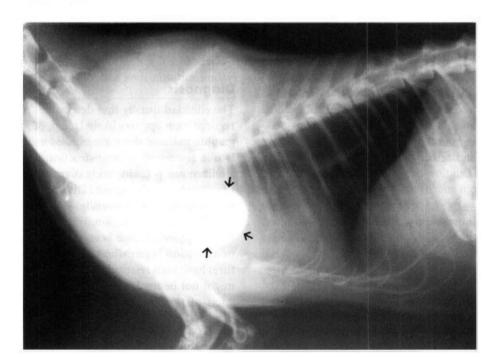

The clinician usually first determines from the history that regurgitation appears likely (see p. 353). Then, after radiographic findings show generalized esophageal dilation that is not associated with obstruction (see Fig. 29-3, A), the clinician can presumptively diagnose esophageal weakness. Diverticula in the cranial thorax caused by esophageal weakness occur occasionally and are often confused with vascular ring obstruction (Fig. 31-1). Congenital, rather than acquired, disease is suspected if the regurgitation and/ or aspiration began when the pet was young. If clinical features have been relatively mild or intermittent, the diagnosis might not be made until the animal is older, but consideration of the history should suggest that signs have been present since the animal was young. Endoscopy is not as useful as contrast radiographs for diagnosing this disorder. Collies may have dermatomyositis, which also causes esophageal weakness. Some breeds (e.g., Miniature Schnauzers, Great Danes, Dalmatians) appear to be at increased

#### **Treatment**

Congenital esophageal weakness currently cannot be cured or resolved by medical therapy, although cisapride (0.25 mg/ kg) seemingly ameliorates signs in rare cases (probably in patients with substantial gastroesophageal reflux). Conservative dietary management is used to try to prevent further dilation and aspiration. Classically, the animal is fed a gruel from an elevated platform that requires the pet to stand on its rear legs. In this manner, the cervical and thoracic esophagus is nearly vertical when food is ingested, which allows gravity to aid food passing through the esophagus and into the stomach. This position should be maintained for 5 to 10 minutes after the animal has finished eating and drinking. If the dog cannot stand, it may be backed into a corner, forced to sit on its haunches, and have its front legs lifted while the corner prevents the dog from falling over. Alternatively, it may be fed on stairs so that it is at least at a 45-degree angle when eating. Feeding several small meals a day also helps prevent esophageal retention.

Some animals do better if fed dry or canned dog food free choice throughout the day from such a platform. It is impossible to predict whether a given dog will respond better to gruel or dry dog food. Therefore trial and error are necessary to determine the diet that works best for a particular animal. In some dogs the dilated esophagus may partially return to normal size and function. Even if the esophagus remains dilated, some dogs may be managed by dietary change and have a good quality of life.

Gastrostomy tubes bypass the csophagus and can provide some relief from regurgitation and/or aspiration. However, animals may still regurgitate saliva and, if there is gastroesophageal reflux, may also regurgitate food. Some animals

**FIG 31-1**Lateral contrast thoracic radiograph of a cat. Note large diverticulum suggestive of obstruction (arrows). This cat had generalized esophageal weakness without obstruction.

with gastrostomy tubes respond well for varying periods of time.

#### **Prognosis**

The prognosis is guarded to poor; some animals respond well, but most have severe regurgitation and/or aspiration symptoms despite all treatment efforts. Aspiration pneumonia is the major cause of death.

#### ACQUIRED ESOPHAGEAL WEAKNESS

# **Etiology**

Acquired esophageal weakness in dogs is usually caused by a neuropathy, myopathy, or junctionopathy (e.g., myasthenia gravis; see Box 28-5). German Shepherds, Golden Retrievers, and Irish Setters might have increased risk. In cats esophagitis may be a cause of acquired esophageal weakness.

#### **Clinical Features**

Acquired esophageal weakness primarily occurs in dogs. The patients usually are presented because of "vomiting" (actually regurgitation), but some present with a cough and little or no obvious regurgitation (e.g., regurgitated material is sometimes reswallowed or re-eaten by the animal). Weight loss may occur if the dog regurgitates most of its food.

#### Diagnosis

The initial diagnostic step is to document that regurgitation, rather than vomiting, is occurring (see p. 353). Acquired esophageal weakness is usually diagnosed by finding general-

ized esophageal dilation without evidence of obstruction on plain and contrast radiographs (see Fig. 29-3, *A*). The severity of clinical signs does not always correlate with the magnitude of radiographic changes. Some symptomatic animals have segmental weakness primarily affecting the cervical esophagus, just behind the cricopharyngeus muscle. However, normal dogs often have minimal amounts of barium retained in this location, so it is important to distinguish insignificant from clinically important retention. It is important to rule out lower esophageal spasm and stricture, which, though very rare, radiographically mimic esophageal weakness but require surgical treatment. Ideally, fluoroscopy should be used to look for evidence of gastroesophageal reflux, which may benefit from prokinetic therapy (e.g., cisapride).

It is important to search for underlying causes of acquired esophageal weakness (see Box 28-5). The titer of antibodies to acetylcholine receptors (indicative of myasthenia gravis) should be measured in dogs. "Localized" myasthenia may affect only the esophagus and/or oropharyngeal muscles. An adrenocorticotropic hormone (ACTH)-stimulation test is indicated to look for otherwise occult hypoadrenocorticism (even if serum electrolyte concentrations are normal). Serum thyroxine, free thyroxine, and thyroid-stimulating hormone (TSH) concentrations may reveal hypothyroidism, which can very rarely be associated with esophageal dysfunction. Tests of thyroid gland function must be interpreted carefully because of potential confusion regarding the euthyroid sick syndrome (see Chapter 51). Electromyography may reveal generalized neuropathies or myopathies. Dysautonomia occurs occasionally and is suspected on the basis of clinical signs (i.e., dilated colon, dry nose, dilated pupils, keratoconjunctivitis sicca, and/or bradycardia that responds poorly to atropine). Gastric outflow obstruction in cats can cause vomiting with secondary esophagitis. Other causes are rarely found (see Box 28-5). If an underlying cause cannot be found, the disease is termed *idiopathic acquired esophageal weakness* (i.e., idiopathic acquired megaesophagus).

#### Treatment

Dogs with acquired megaesophagus caused by localized myasthenia gravis or hypoadrenocorticism often respond to appropriate therapy (see Chapters 53 and 71). Localized myasthenia seems ultimately to respond best to immunosuppressive therapy (e.g., azathioprine), although pyridostigmine may help initially. Gastroesophageal reflux may respond to prokinetic and antacid therapy (cisapride at 0.25 mg/kg and omeprazole at 0.7 to 1.5 mg/kg are preferred). If the disease is idiopathic, conservative dietary therapy as described for congenital esophageal weakness is the only recourse. Although some dogs with congenital esophageal weakness regain variable degrees of esophageal function, this is rare in those with idiopathic acquired esophageal weakness. Severe esophagitis may cause secondary esophageal weakness, which resolves after appropriate therapy (discussed in more detail later in this chapter). Gastrostomy tubes diminish the potential for aspiration, ensure positive nitrogen balance, and help treat esophagitis if present. Some dogs benefit from the longterm use of a gastrostomy tube, but others continue to regurgitate and aspirate as a result of severe gastroesophageal reflux or simply the accumulation of large amounts of saliva in the esophagus.

#### **Prognosis**

All animals with acquired esophageal weakness are at risk for aspiration pneumonia and sudden death. If the underlying cause can be treated and the esophageal dilation and weakness can be resolved, the prognosis is good because the risk of aspiration is eliminated. The prognosis is guarded if the animal with idiopathic megaesophagus responds to dietary management (it is still at risk) and very poor if the animal does not respond to this protocol.

#### **ESOPHAGITIS**

#### Etiology

Esophagitis is principally caused by gastroesophageal reflux, persistent vomiting of gastric acid, esophageal foreign objects, and caustic agents. Pills (e.g., tetracycline) may be retained in the esophagus if they are not washed down with water or food and are thought to cause severe esophagitis in cats. An association between distal esophagitis (ostensibly caused by gastroesophageal reflux) and upper respiratory disease in brachycephalic dogs has been suggested.

#### **Clinical Features**

Regurgitation is expected, although anorexia and drooling may predominate if swallowing is painful. If a caustic agent (e.g., disinfectant) is ingested, the mouth and tongue are often hyperemic and/or ulcerated; anorexia is the primary sign.

# Diagnosis

A history of vomiting followed by both vomiting and regurgitation suggests esophagitis secondary to excessive exposure to gastric acid. This sign may occur in parvoviral enteritis and in various other disorders. Likewise, regurgitation or anorexia begining shortly after an anesthetic procedure may indicate esophagitis caused by reflux. Plain and contrast radiographs may reveal hiatal hernias, gastroesophageal reflux, or esophageal foreign bodies. Contrast esophagrams do not reliably detect esophagitis; esophagoscopy with or without biopsy is needed to establish a definitive diagnosis.

#### **Treatment**

Decreasing gastric acidity, preventing reflux of gastric contents into the esophagus, and protecting the denuded esophagus are the hallmarks of treatment. H2 receptor antagonists (see Table 30-4) may be used, but proton pump inhibitors (e.g., omeprazole) are superior for decreasing gastric acidity, a critical factor in these animals. However, because it may take 2 to 5 days for omeprazole to achieve maximum efficacy, famotidine may be used concurrently during initial therapy. Metoclopramide stimulates gastric emptying, resulting in less gastric volume to reflux into the esophagus, but cisapride (0.25 to 0.5 mg/kg) tends to be more effective. Sucralfate (particularly suspensions) might protect denuded esophageal mucosa (see Table 30-5), but its usefulness is unknown. Antibiotics effective against anaerobes (e.g., amoxicillin, clindamycin; see Drugs Used in Gastrointestinal Disorders, pp. 481-483) have been used but are of unknown value. A gastrostomy feeding tube helps to protect the esophagus while the mucosa is healing and ensures a positive nitrogen balance. Corticosteroids (e.g., prednisolone, 1.1 mg/kg/day) may be administered in an attempt to prevent cicatrix, but their efficacy is dubious. Hiatal hernias may need to be surgically repaired.

### Prognosis

The prognosis depends on the severity of the esophagitis and whether an underlying cause can be identified and controlled. Early, aggressive therapy helps to prevent cicatrix formation and allows a better prognosis.

## **HIATAL HERNIA**

# **Etiology**

Hiatal hernia is a diaphragmatic abnormality that allows part of the stomach (usually the cardia) to prolapse into the thoracic cavity. In severe cases it allows gastroesophageal reflux. The condition seems to be primarily congenital.

#### **Clinical Features**

Sharpei dogs seem to be predisposed to this disorder. Regurgitation is the primary sign in symptomatic individuals, but some animals are asymptomatic.

## **Diagnosis**

Plain radiographs or positive-contrast esophagrams may reveal gastric herniation into the thorax (Fig. 31-2); however, herniation may be intermittent and difficult to detect. It is sometimes necessary to put pressure on the abdomen during the radiographic procedure to cause displacement of the stomach during the study. Hiatal hernias are occasionally found endoscopically.

#### **Treatment**

If the hiatal hernia is symptomatic at an early age, surgery is more likely to be required to correct it. If signs of hiatal hernia first appear later in life, aggressive medical management of gastroesophageal reflux (e.g., cisapride, omeprazole) is often sufficient. If medical management is not successful, surgery can be considered.

## **Prognosis**

The prognosis is often good after surgical repair (congenital cases) or aggressive medical management (acquired cases).

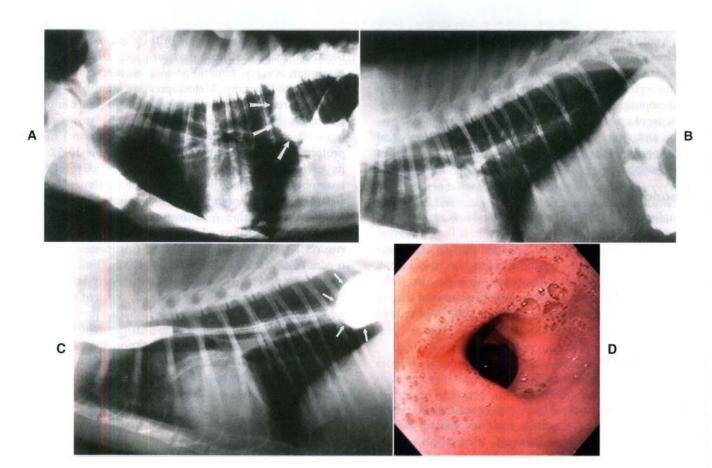

#### **DYSAUTONOMIA**

# **Etiology**

Dysautonomia in dogs and cats is an idiopathic condition that causes loss of autonomic nervous system function. In at least some circumstances, it may be due to a clostridial toxin.

#### **Clinical Features**

Clinical signs vary substantially. Megaesophagus and subsequent regurgitation are common (not invariable); however, dysuria and a distended urinary bladder, mydriasis and lack

#### FIG 31-2

of pupillary light response, dry mucous membranes, weight loss, constipation, vomiting, poor anal tone, and/or anorexia have all been reported. There appear to be geographic areas (e.g., Missouri and surrounding states) that currently have an increased incidence of the disease.

# **Diagnosis**

Dysautonomia is usually first suspected clinically by finding dysuria, dry mucous membranes, and abnormal pupillary light responses. Radiographs revealing distention of multiple areas of the alimentary tract (e.g., esophagus, stomach, small intestine) also are suggestive. A presumptive, antemortem diagnosis is usually made by observing the effects of pilocarpine on pupil size after 1 to 2 drops of 0.05% pilocarpine are placed in one eye only. Finding that the treated eye rapidly constricts whereas the untreated eye does not is consistent with dysautonomia. Similarly, finding that a dysuric dog with a large urinary bladder can urinate after subcutaneous administration of 0.04 mg bethanechol/kg is also suggestive (although not all affected animals respond). Definitive diagnosis requires histopathology of autonomic ganglia, which can be obtained only at necropsy.

#### **Treatment**

Treatment is palliative. Bethanechol can be given (1.25 to 5 mg once daily) to aid in urinary evacuation. The urinary bladder should be expressed as needed. Gastric prokinetics (e.g., cisapride) may help lessen vomiting. Antibiotics may be administered for aspiration pneumonia secondary to megaesophagus.

### **Prognosis**

The prognosis is usually grim.

#### **ESOPHAGEAL OBSTRUCTION**

## **VASCULAR RING ANOMALIES**

## **Etiology**

Vascular ring anomalies are congenital defects. An embryonic aortic arch persists, trapping the esophagus in a ring of tissue. Persistent right fourth aortic arch (PRAA) is the most commonly recognized vascular anomaly (see Chapter 5).

# **Clinical Features**

Vascular ring anomalies occur in both dogs and cats. Regurgitation is the most common presenting complaint, although signs of aspiration may occur. Clinical features often begin shortly after the animal eats solid food for the first time. Some animals have relatively minor clinical signs and are not diagnosed until they are several years old.

### **Diagnosis**

Definitive diagnosis is usually made by contrast esophagram (see Fig. 29-3, *B*). Typically, the esophagus cranial to the heart is dilated, whereas the esophagus caudal to the heart is

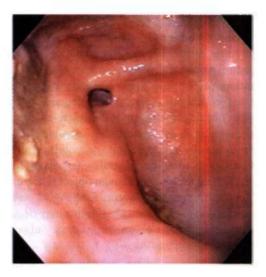

FIG 31-3
Endoscopic view of an esophageal lumen constricted by an extramural vascular ring anomaly.

normal. In rare cases the entire esophagus is dilated (the result of concurrent megaesophagus) except for a narrowing at the base of the heart. It has been suggested that if focal leftward deviation of the trachea is seen at the cranial border of the heart in the ventrodorsal or dorsoventral projections, this is sufficient to diagnose PRAA in young dogs that are regurgitating food. Endoscopically, the esophagus has an extramural narrowing (Fig. 31-3; i.e., not a mucosal proliferation or scar) near the base of the heart.

#### **Treatment**

Surgical resection of the anomalous vessel is necessary. Conservative dietary management (i.e., gruel diet) by itself is inappropriate because the dilation will persist and probably progress. In particular, the animal will be at risk for foreign body occlusion at the site of the PRAA. Dietary therapy may benefit some animals postoperatively.

#### **Prognosis**

Most patients improve dramatically after surgery. However, there are exceptions, and the more severe the preoperative dilation, the more likely regurgitation will continue postoperatively. Some dogs have concomitant esophageal weakness. A guarded prognosis is appropriate. If a postsurgical stricture occurs, esophageal ballooning or a second surgical procedure may be considered.

#### **ESOPHAGEAL FOREIGN OBJECTS**

#### Etiology

Almost anything may lodge in the esophagus, but objects with sharp points (e.g., bones, fishhooks) are probably most common. Most obstructions occur at the thoracic inlet, the base of the heart, or immediately in front of the diaphragm.

#### **Clinical Features**

Dogs are more commonly affected because of their less discriminating eating habits. Regurgitation or anorexia secondary to esophageal pain is common. Acute onset of regurgitation (as opposed to vomiting) is suggestive of esophageal foreign body. Clinical signs depend on where the obstruction occurs, whether it is complete or partial, and whether esophageal perforation has occurred. Complete obstructions cause regurgitation of solids and liquids, whereas partial obstructions may allow passage of liquids to the stomach. If an esophageal foreign object is impinging on airways, acute dyspnea may occur. Esophageal perforation usually causes fever and anorexia; dyspnea may occur as the result of pleural effusion or pneumothorax. Subcutaneous emphysema rarely occurs.

## **Diagnosis**

Plain thoracic radiographs reveal most esophageal foreign bodies (see Fig. 29-2), although the clinician may have to search carefully to find poultry bones or other food items that are even less radiodense. It is also important to look for evidence of esophageal perforation (i.e., pneumothorax, pleural effusion, fluid in the mediastinum). Esophagrams are rarely necessary; esophagoscopy is diagnostic and typically therapeutic.

#### **Treatment**

Foreign objects are best removed endoscopically unless (1) they are too firmly lodged to pull free or (2) radiographs suggest perforation. Thoracotomy is indicated in these two situations, although in rare cases perforations may be treated medically. Objects that cannot be moved should not be pulled on vigorously because of the risk of creating or enlarging a perforation. An object should be pushed into the stomach only when the clinician is confident that there are no sharp edges on the other side of the foreign object. During the procedure the esophagus should be insufflated carefully to avoid rupturing weakened areas or causing tension pneumothorax. After an object has been removed, the esophageal mucosa should be reexamined endoscopically to evaluate the damage caused by the object. Thoracic radiographs should be repeated to look for pneumothorax, an indication of perforation. Treatment after foreign body removal may include antibiotics, H<sub>2</sub> receptor antagonists or proton pump inhibitors, prokinetic agents, gastrostomy feeding tube, and/or corticosteroids (prednisolone, 1.1 mg/kg/day), depending on residual damage. Perforation usually requires thoracotomy to clean out septic debris and close the esophageal defect.

#### **Prognosis**

The prognosis for animals with esophageal foreign bodies without perforation is usually good, but the presence of perforation warrants a guarded prognosis depending on the severity of thoracic contamination. Cicatrix formation with obstruction is possible if substantial mucosal damage occurs.

## **ESOPHAGEAL CICATRIX**

## **Etiology**

Prior esophagitis from any cause may produce a stricture. Severe, deep inflammation of the esophagus (e.g., subsequent to foreign bodies or severe gastroesophageal reflux) is usually required for cicatrix to occur.

#### **Clinical Features**

Esophageal cicatrix occurs in both dogs and cats. The main sign is regurgitation (especially of solids). Some animals are clinically anorexic as a result of pain experienced when food becomes lodged at the stricture by forceful esophageal peristalsis.

# Diagnosis

Partial obstructions may be difficult to diagnose. Positive-contrast esophagrams (often using barium mixed with food) are necessary (Fig. 31-4). Esophagoscopy is definitive, but a partial stricture may not be obvious in large dogs unless the endoscopist is experienced and the esophagus is carefully inspected.

#### **Treatment**

Treatment consists of correcting the suspected cause (e.g., esophagitis) and/or widening the stricture by ballooning or bougienage. Surgical resection is not recommended because iatrogenic strictures at the anastomotic site are common. Ballooning is less traumatic, has less chance of perforation,

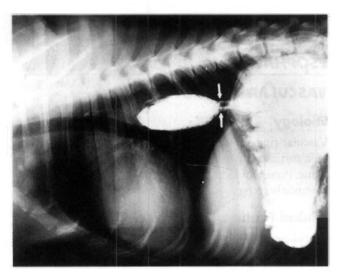

FIG 31-4

Lateral contrast esophagram using liquid barium mixed with moist food. Partial stricture (arrows) is preventing the bolus from readily entering the stomach. This stricture was not detected with barium paste, even when viewed fluoroscopically. However, when the barium-food mixture was used, the stricture was obvious and material was retained for minutes before passing. Endoscopically, there was a band of fibrous connective tissue at this spot.

and may be accomplished during esophagoscopy. Angioplasty catheters or esophageal dilation balloons are more useful than Foley catheters because the former are less likely to slide to one side of the obstruction during inflation. Bougienage can more easily cause a rupture, but it is relatively safe and equally effective if done by a trained individual. After the stricture has been dilated, antibiotics and/or corticosteroids (prednisolone, 1.1 mg/kg/day) are often administered to help prevent infection and stricture reformation; however, their efficacy is unknown. Intralesional steroid injections performed endoscopically have been tried in severe cases, but their value is uncertain at this time. If esophagitis is present, it should be treated aggressively. Some animals are cured after one ballooning, whereas others require multiple procedures.

Early identification and appropriate treatment of highrisk animals (i.e., those with severe esophagitis or after foreign object removal) help decrease the likelihood of stricture formation. Resolving esophagitis decreases inflammation and lessens fibrous connective tissue formation. The efficacy of corticosteroids is uncertain, but they are worth trying in selected cases.

#### **Prognosis**

The shorter the length of esophagus involved and the sooner the corrective procedure is performed, hopefully the better the prognosis. Animals with extensive, mature strictures and/or continuing esophagitis often need repeated dilatory procedures and have a more guarded prognosis. Most animals with benign esophageal strictures can be helped. Long-term gastrostomy tubes may be necessary in some animals.

#### **ESOPHAGEAL NEOPLASMS**

## Etiology

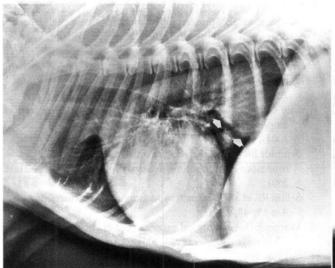

Primary esophageal sarcomas in dogs are often due to *Spirocerca lupi*. Primary esophageal carcinomas are of unknown etiology. Leiomyomas and leiomyosarcomas are found at the lower esophageal sphincter in older dogs. Thyroid carcinomas and pulmonary alveolar carcinomas may invade the esophagus in dogs. Squamous cell carcinomas are the most common esophageal neoplasm in cats.

#### **Clinical Features**

Dogs and cats with primary esophageal tumors may be asymptomatic until the tumor is far advanced, and these animals are diagnosed fortuitously when thoracic radiographs are obtained for other reasons. Regurgitation, anorexia, and/or fetid breath may occur if the tumor is large or causes esophageal dysfunction. If the esophagus is involved secondarily, clinical signs may result from esophageal dysfunction or tumor effects on other tissues.

# **Diagnosis**

Plain thoracic radiographs may reveal a soft tissue density in the caudal lung fields. These tumors may be difficult to discern radiographically from pulmonary lesions and usually require contrast esophagrams to make this distinction (Fig. 31-5). Esophagoscopy easily locates intraluminal and intramural masses (Fig. 31-6) or strictures and is sensitive in finding extraluminal masses causing esophageal stricture (i.e., the endoscopist will not be able to normally distend the esophageal lumen). Retroflexing the tip of an endoscope

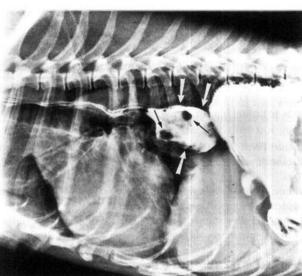

FIG 31-5

A, Lateral thoracic radiograph of a dog with a previously unsuspected mass (arrows) not obviously associated with the esophagus. B, Contrast esophagram in the same dog demonstrates that the esophagus is dilated (large arrows) and that there are intraesophageal filling defects (small arrows) in this dilated area. This dog had a primary esophageal carcinoma. (A from Allen D, editor: Small animal medicine, Philadelphia, 1991, JB Lippincott.)

В

while it is within the stomach is the best method of identifying lower esophageal sphincter leiomyomas and leiomyosarcomas.

#### **Treatment**

Surgical resection is rarely curative (except for leiomyomas at the lower esophageal sphincter) because of the advanced nature of most esophageal neoplasms when they are diagnosed. Resection may be palliative. Photodynamic therapy may be beneficial in dogs and cats with small superficial esophageal neoplasms.

#### **Prognosis**

The prognosis is usually poor.

Idiopathic Gastric Hypomotility Bilious Vomiting Syndrome

GASTROINTESTINAL ULCERATION/EROSION INFILTRATIVE GASTRIC DISEASES

Neoplasms Pythiosis

# **GASTRITIS**

# **ACUTE GASTRITIS**

## Etiology

Ingestion of spoiled or contaminated foods, foreign objects, toxic plants, chemicals, and/or irritating drugs (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) are common causes of acute gastritis. Infectious, viral, and bacterial causes occur but are not well defined in dogs and cats.

#### **Clinical Features**

Dogs are more commonly affected than cats by acute gastritis, probably because of their less discriminating eating

habits. Signs usually consist of acute onset of vomiting; food and bile are typically vomited, although small amounts of blood may be present. Affected animals are typically uninterested in food and may or may not feel sick. Fever and abdominal pain are uncommon.

# Diagnosis

Unless the animal was seen eating some irritative substance, acute gastritis is usually a presumptive diagnosis of exclusion based on history and physical examination findings. Abdominal imaging and/or clinical pathologic data are indicated if the animal is severely ill or if other disease is suspected. After alimentary foreign body, obstruction, parvoviral enteritis, uremia, diabetic ketoacidosis, hypoadrenocorticism, hepatic disease, hypercalcemia, and pancreatitis are ruled out, acute gastritis is a reasonable tentative diagnosis. If the anorexia/vomiting resolves after 1 to 2 days of symptomatic and supportive therapy, the tentative diagnosis is generally assumed to be correct (pancreatitis is still possible; see Chapter 40). Gastroscopy in such animals might reveal bile or gastric erosions/hyperemia.

Because acute gastritis is a diagnosis of exclusion and its signs are suggestive of various other disorders (e.g., foreign bodies, intoxication), good history taking and physical examination are mandatory. The owner should monitor the pet, and if the animal's condition worsens or does not improve within 1 to 3 days, imaging, a complete blood count (CBC), a serum biochemistry profile, and urinalysis are indicated.

#### **Treatment**

Parenteral fluid therapy and the withholding of food and water for 24 hours often suffice to control vomiting. If the vomiting persists or is excessive, or if the animal becomes depressed because of the vomiting, central-acting antiemetics (e.g., prochlorperazine, ondansetron, maropitant) may be administered parenterally (see p. 404). When feeding begins, small amounts of cool water are offered frequently. If the animal drinks without vomiting, small amounts of a bland diet (e.g., one part cottage cheese and two parts potato; one part boiled chicken and two parts potato) are offered. Antibiotics and corticosteroids are rarely indicated.

# **Prognosis**

The prognosis is excellent as long as the fluid and electrolyte balance is maintained.

#### **HEMORRHAGIC GASTROENTERITIS**

# Etiology

The cause of hemorrhagic gastroenteritis is unknown.

## **Clinical Features**

Hemorrhagic gastroenteritis occurs in dogs and is more severe than acute gastritis, typically causing profuse hematemesis and/or hematochezia. Classically occurring in smaller breeds that have not had access to garbage, this disorder has an acute course that can rapidly produce a critically ill animal. In severe cases the animal may be moribund by the time of presentation.

## Diagnosis

These animals are typically hemoconcentrated (i.e., packed cell volume  $[PCV] \ge 55\%$ ) with normal plasma total protein concentrations. The acute onset of typical clinical signs plus marked hemoconcentration allows a presumptive diagnosis. Thrombocytopenia and renal or prerenal azotemia may be seen in severely affected animals.

#### Treatment

Aggressive fluid therapy is initiated to treat or prevent shock, disseminated intravascular coagulation (DIC) secondary to hypoperfusion, and renal failure secondary to hypovolemia. Parenteral antibiotics (e.g., ampicillin, chloramphenicol; see pp. 481–483) are often used because of the fear that intestinal bacteria are proliferating, but their value has not been definitively established. If the patient becomes severely hypoalbuminemic during fluid therapy, synthetic colloids or plasma may be required.

### **Prognosis**

The prognosis is good for most animals that are presented in a timely fashion. Inadequately treated animals may die as a result of circulatory collapse, DIC, and/or renal failure.

### **CHRONIC GASTRITIS**

# Etiology

There are several types of chronic gastritis (e.g., lymphocytic/plasmacytic, eosinophilic, granulomatous, atrophic). Lymphocytic-plasmacytic gastritis might be an immune and/or inflammatory reaction to a variety of antigens. Helicobacter organisms might be responsible for such a reaction in some animals (especially cats). Physaloptera rara has seemingly been associated with a similar reaction in some dogs. Eosinophilic gastritis may represent an allergic reaction, probably to food antigens. Atrophic gastritis may be the result of chronic gastric inflammatory disease and/or

immune mechanisms. Ollulanus tricuspis may cause granulomatous gastritis in cats.

#### **Clinical Features**

Chronic gastritis appears to be more common in cats than in dogs and may or may not be associated with chronic enteritis (e.g., inflammatory bowel disease). Anorexia and vomiting are the most common signs in affected dogs and cats. The frequency of vomiting varies from once weekly to many times per day. Some animals have only anorexia, ostensibly as a result of low-grade nausea.

# Diagnosis

Clinical pathologic findings are not diagnostic, although eosinophilic gastritis inconsistently causes peripheral eosinophilia. Imaging sometimes documents mucosal thickening. Diagnosis requires gastric mucosal biopsy, and endoscopy is the most cost-effective method of obtaining these samples. Gastritis may be very localized, and endoscopy allows multiple biopsies over the entire mucosal surface, whereas surgical biopsy typically results in one sample that is taken blindly. Gastric biopsy should always be performed, regardless of the visual mucosal appearance. It must be remembered that enteritis is far more common than gastritis (which is why duodenal biopsies are usually more important than gastric biopsies). Gastric lymphoma can be surrounded by lymphocytic inflammation, and obtaining inappropriately superficial biopsy specimens may result in an incorrect diagnosis of inflammatory disease. Appropriate use of a scope with a 2.8-mm biopsy channel will usually prevent this misdiagnosis (unless the tumor is in the muscular layers of the stomach). Meaningful histopathologic interpretation of alimentary tissue can be difficult; the clinician should not hesitate to request a second histologic opinion if the diagnosis does not fit the patient or the response (or lack thereof) to therapy. If Ollulanus tricuspis is suspected, vomitus or gastric washings should be examined for the parasites, but they might also be found in gastric biopsy specimens. Physaloptera organisms are visible endoscopically.

#### Treatment

Lymphocytic-plasmacytic gastritis sometimes responds to dietary therapy (e.g., low-fat, low-fiber, elimination diets) alone (see p. 397). If such therapy is inadequate, corticosteroids (e.g., prednisolone, 2.2 mg/kg/day) can be used concurrently. Even if corticosteroids are required, dietary therapy may ultimately allow one to administer a substantially decreased dose, thus avoiding glucocorticoid adverse effects. If corticosteroid therapy is necessary, the dose should be gradually decreased to find the lowest effective dose. However, the dose should not be tapered too quickly after obtaining a clinical response or the clinical signs may return and be more difficult to control than they were initially. In rare cases, azathioprine or similar drugs will be necessary (see Chapter 30). Concurrent use of H<sub>2</sub> receptor antagonists is

sometimes beneficial. Ulceration should be treated as discussed on page 436.

Canine eosinophilic gastritis usually responds well to a *strict* elimination diet.If dietary therapy alone fails, corticosteroid therapy (e.g., prednisolone, 1.1 to 2.2 mg/kg/day) in conjunction with diet is usually effective. Feline hypereosinophilic syndrome responds poorly to most treatments.

Atrophic gastritis and granulomatous gastritis are more difficult to treat than lymphocytic-plasmacytic or canine eosinophilic gastritis. Diets low in fat and fiber (e.g., one part cottage cheese and two parts potato) may help control signs. Atrophic gastritis may respond to antiinflammatory, antacid, and/or prokinetic therapy; the latter is designed to keep the stomach empty, especially at night. Granulomatous gastritis is uncommon in dogs and cats and does not respond well to dietary or corticosteroid therapy.

# **Prognosis**

The prognosis for canine and feline lymphocytic-plasmacytic gastritis is often good with appropriate therapy. Some researchers have suggested that lymphoma has been known to develop in cats with lymphocytic gastritis; however, it is possible that the original diagnosis of lymphocytic gastritis was incorrect or that lymphoma developed independently of the gastritis.

The prognosis for canine eosinophilic gastritis is typically good. Feline eosinophilic gastritis can be a component of hypereosinophilic syndrome, which typically responds poorly to treatment. Hypereosinophilic syndrome has a guarded prognosis.

## HELICOBACTER-ASSOCIATED DISEASE

## **Etiology**

Helicobacter pylori is the principal spirochete found in human gastric mucosa, whereas Helicobacter felis, Helicobacter heilmannii, Helicobacter bizzozeronii, and Helicobacter salomonis may be the principal gastric spirochetes in dogs and cats. However, H. pylori has been found in cats.

## **Clinical Features**

People with symptomatic *H. pylori* infections usually develop ulceration and gastritis with neutrophilic infiltrates. They can also develop a lymphocytic lesion that is indistinguishable from lymphoma but that can be cured with antibiotic therapy. Dogs and cats with gastric *Helicobacter* infections may have nausea, anorexia, and/or vomiting associated with lymphocytic and occasionally neutrophilic infiltrates; however, most dogs and cats with gastric *Helicobacter* infections are asymptomatic. Because so many infected animals are asymptomatic, the cause and effect have not been clearly established between *Helicobacter* organisms and canine or feline gastric disease. Cats colonized with *H. pylori* seem to have more severe histologic lesions than those with *H. felis*, which in turn may be associated with more severe lesions than those with *H. heilmannii*. Reasonable anecdotal

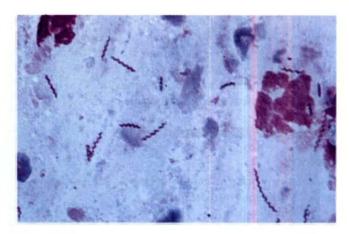

FIG 32-1
Air-dried smear of gastric mucosa obtained endoscopically and stained with Diff-Quik. Numerous spirochetes are seen. The affected dog was vomiting because of an ulcerated leiomyoma, and the spirochetes did not appear to be causing disease in this animal. (Magnification ×1000.)

evidence seems to suggest that some ill animals with gastric *Helicobacter* infections have their signs resolve when the organism is eliminated. Whether the "cure" is due to the elimination of *Helicobacter* organisms or something else remains in question, but it seems reasonable to assume that *Helicobacter* organisms cause disease in some animals.

# **Diagnosis**

Gastric biopsy is currently required for a diagnosis of *Helicobacter* infection. The organisms are easy to identify if the pathologist is looking for them and uses special stains (e.g., Giemsa, Warthin-Starry). The bacteria are not uniformly distributed throughout the stomach, and it is best to obtain biopsy specimens from the body, fundus, and antrum. The clinician may also diagnose this infection by cytologic evaluation of the gastric mucosa (Fig. 32-1) or by looking for gastric mucosal urease activity (see Chapter 29). Because of the uncertain pathogenicity of *Helicobacter* spp., the clinician is advised to look first for other, better explanations for the animal's clinical signs before deciding that a *Helicobacter* organism is causing disease.

#### **Treatment**

A combination of metronidazole, amoxicillin, and either famotidine or bismuth (either subsalicylate or subcitrate) seems to be effective in veterinary patients. Azithromycin and claritromycin have been substituted for bismuth in cats. Anecdotally, some animals seem to respond to just erythromycin or amoxicillin. Therapy should probably last for at least 10 days.

#### **Prognosis**

Animals with apparent *Helicobacter*-associated disease seem to respond well to treatment and have a good progno-

sis. However, because the cause and effect are uncertain, any animal that does not respond to therapy should be reexamined carefully to determine if other diseases are present. Recurrence of infection after treatment occurs, but it is not clear whether this represents a relapse of the original infection or reinfection from an outside sourse.

# PHYSALOPTERA RARA

## Etiology

Physaloptera rara is a nematode that has an indirect life cycle; beetles are the intermediate hosts.

#### **Clinical Features**

A single *Physaloptera rara* parasite can cause intractable vomiting. The parasite is primarily found in dogs. The vomiting usually does not resolve with antiemetics. Vomitus may or may not contain bile, and affected animals appear otherwise healthy.

# **Diagnosis**

Ova are seldom found in feces. Furthermore, sodium dichromate or magnesium sulfate solutions are usually necessary to identify the eggs in feces. Most diagnoses are made when the parasites are found during gastroduodenoscopy (see Fig. 29-25). There may be only one worm causing clinical signs, and it can be difficult to find, especially if it is attached within the pylorus. Alternatively, empirical treatment (as described here) is reasonable.

#### **Treatment**

Pyrantel pamoate or ivermectin is usually effective. If the parasite is found during endoscopy, it can be removed with forceps.

## **Prognosis**

The vomiting usually stops as soon as the worms are removed or eliminated.

## **OLLULANUS TRICUSPIS**

## Etiology

Ollulanus tricuspis is a nematode with a direct life cycle that is transmitted via vomited material.

#### **Clinical Features**

Cats are the most commonly affected species, although dogs and foxes are occasionally infected. Vomiting is the principal clinical sign, but clinically normal cats may harbor the parasite. Gross gastric mucosal lesions may or may not be seen in infested cats.

## Diagnosis

Cattery situations promote infection because the parasite is passed directly from one cat to another. However, occasionally cats with no known contact with other cats are infected. Looking for parasites in gastric washings or vomited material with a dissecting microscope is the best means of diagnosis. The parasite can be seen occasionally in gastric mucosal biopsy specimens.

# **Treatment/Prognosis**

Therapy is uncertain, but oxfendazole (10 mg/kg, orally administered q12h for 5 days) or fenbendazole might be effective. Occasionally, animals have severe gastritis and become debilitated.

# GASTRIC OUTFLOW OBSTRUCTION/ GASTRIC STASIS

# BENIGN MUSCULAR PYLORIC HYPERTROPHY (PYLORIC STENOSIS)

# Etiology

The cause of benign muscular pyloric hypertrophy has not been definitively established, although some experimental research suggests that gastrin promotes the development of pyloric stenosis.

# **Clinical Features**

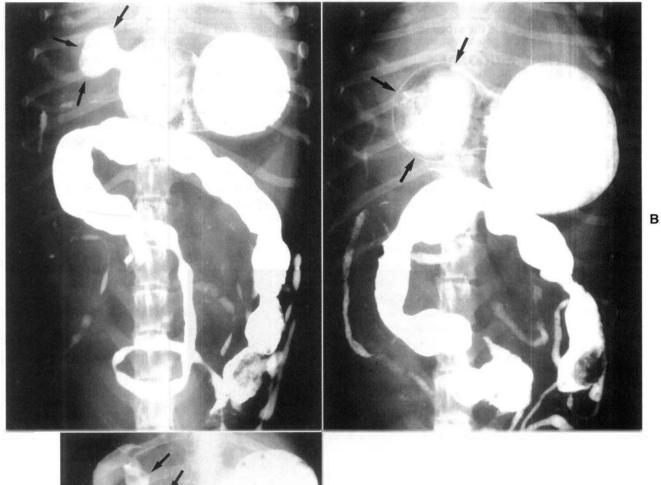

Benign muscular pyloric stenosis typically causes persistent vomiting in young animals (especially brachycephalic dogs and Siamese cats) but can be found in any animal. These animals usually vomit food shortly after eating. The vomiting is sometimes described as projectile. The animals are otherwise clinically normal, although some pets may lose weight. Some cats with pyloric stenosis vomit so much that secondary esophagitis, megaesophagus, and regurgitation occur, confusing the clinical picture. Hypochloremic, hypokalemic, metabolic alkalosis sometimes occurs, but it is inconsistent and nonspecific for gastric outflow obstruction.

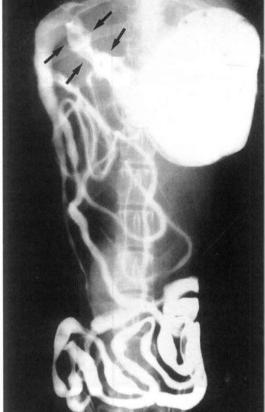

## Diagnosis

Diagnosing pyloric stenosis requires first finding gastric outflow obstruction during barium contrast-enhanced radiographs (Fig. 32-2), ultrasonography, gastroduodenoscopy, and/or exploratory surgery. Infiltrative disease of the pyloric mucosa then must be ruled out through biopsy. Endoscopically, the clinician may see prominent folds of normal-appearing mucosa at the pylorus. At surgery the serosa appears normal, but the pylorus is usually thickened when palpated. The surgeon can open the stomach and try to pass a finger through the pylorus to assess its patency. Extraalimentary tract diseases causing vomiting (see Box 28-6) should also be eliminated.

### **Treatment**

Surgical correction is indicated. Pyloroplasty (e.g., a Y-U-plasty) is more consistently effective than pyloromyotomy. However, improperly performed pyloroplasty or pyloromyotomy can cause perforation or obstruction. Furthermore, the clinician should not routinely do a pyloric outflow procedure whenever an exploratory procedure fails to reveal another cause of vomiting.

A

С

### FIG 32-2

A and B, Ventrodorsal contrast radiographs of a dog with a gastric outflow obstruction. These radiographs were obtained approximately 3 hours after barium administration. There is inadequate gastric emptying despite obvious peristalsis. Note the smooth contour of barium in the antrum (arrows), which is in contrast to C. This is a case of pyloric stenosis. C, Dorsoventral contrast radiographs of a dog with gastric adenocarcinoma. The antrum has an irregular outline but is not distended (arrows). This failure to distend persisted on multiple radiographs and indicates an infiltrative lesion.

## **Prognosis**

Surgery should be curative, and the prognosis is good.

# GASTRIC ANTRAL MUCOSAL HYPERTROPHY

# **Etiology**

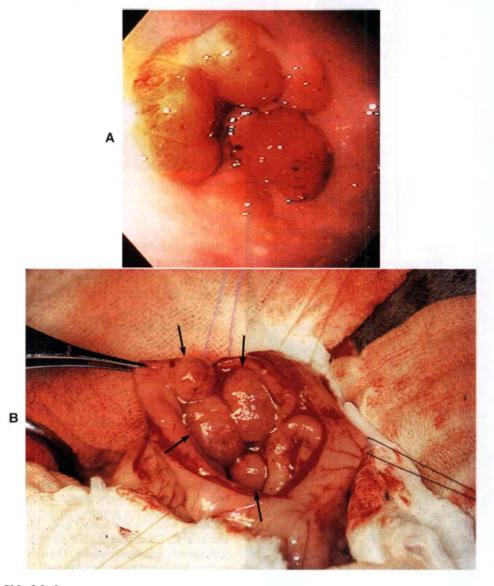

Antral mucosal hypertrophy is idiopathic. Gastric outflow obstruction is caused by excessive, nonneoplastic mucosa that occludes the distal gastric antrum (Fig. 32-3). This disorder is different from benign muscular pyloric stenosis, in which the mucosa is thrown up into folds secondary to the submucosal thickening.

#### **Clinical Features**

Principally found in older, small-breed dogs, antral hypertrophy clinically resembles pyloric stenosis (i.e., animals usually vomit food, especially after meals).

# **Diagnosis**

Gastric outlet obstruction is diagnosed radiographically, ultrasonographically, or endoscopically; however, definitive diagnosis of antral mucosal hypertrophy requires biopsy. Endoscopically, the antral mucosa is redundant and may resemble a submucosal neoplasm causing convoluted mucosal folds. In some cases the mucosa will be obviously reddened and inflamed. However, the mucosa in dogs with

**FIG 32-3 A,** Endoscopic view of the pyloric region of a dog that has gastric antral mucosal hypertrophy. If biopsy is not performed, these folds may easily be mistaken for neoplasia. **B,** Intraoperative photograph of a dog's opened pylorus. Note the numerous folds of mucosa that are protruding (arrows) as a result of gastric antral mucosal hypertrophy.

antral hypertrophy is usually not as firm or hard as expected in those with infiltrative carcinomas or leiomyomas. If antral mucosal hypertrophy is seen at surgery, there should be no evidence of submucosal infiltration or muscular thickening suggestive of neoplasia or benign pyloric stenosis, respectively. It is important to differentiate mucosal hypertrophy from these other diseases so that therapeutic recommendations are appropriate (e.g., gastric carcinomas typically have a worse prognosis, and surgery is not always indicated).

## **Treatment**

Antral mucosal hypertrophy is treated by mucosal resection, usually combined with pyloroplasty. Pyloromyotomy alone may be insufficient to resolve clinical signs from mucosal hypertrophy.

## **Prognosis**

The prognosis is excellent.

#### **GASTRIC FOREIGN OBJECTS**

## **Etiology**

Objects that can pass through the esophagus may become a gastric or intestinal foreign object. Subsequently, vomiting may result from gastric outlet obstruction, gastric distention, or irritation. Linear foreign objects whose orad end lodges at the pylorus may cause intestinal perforation with subsequent peritonitis and must be dealt with expeditiously (see the section on intestinal obstruction on p. 464).

# **Clinical Features**

Dogs are affected more commonly than cats because of their less discriminating eating habits. Vomiting (not regurgitation) is a common sign, but some animals demonstrate only anorexia, whereas others are asymptomatic.

# Diagnosis

Acute onset of vomiting in an otherwise normal animal, especially a puppy, suggests foreign body ingestion. The clinician might palpate an object during physical examination or see it during plain radiographic imaging. Imaging and endoscopy are the most reliable means of diagnosis. However, diagnosis can be difficult if the stomach is filled with food. Some diseases closely mimic obstruction caused by foreign objects; canine parvovirus may initially cause intense vomiting, during which time viral particles might not be detected in the feces. Hypokalemic, hypochloremic, metabolic alkalosis is consistent with gastric outflow obstruction; however, these changes may be absent in animals with gastric obstruction and present in animals without obstruction. Therefore these electrolyte changes are neither sensitive nor specific for gastric outflow obstruction.

## Treatment

Small foreign objects that are unlikely to cause trauma may pass through the gastrointestinal tract. If there is doubt, it is best to remove the object in question. Vomiting can be induced (e.g., apomorphine in the dog, 0.02 or 0.1 mg/kg administered intravenously or subcutaneously, respectively; hydrogen peroxide in the dog, 1 to 5 ml of 3% solution/kg administered orally; xylazine in the cat, 0.4 to 0.5 mg/kg administered intravenously) to eliminate gastric foreign objects if the clinician believes that the object will not cause problems during forcible ejection (i.e., it does not have sharp edges or points and is small enough to pass easily). If there is doubt as to the safety of this approach, the object should be removed endoscopically or surgically.

Before the animal is anesthetized for surgery or endoscopy, the electrolyte and acid-base status should be evaluated. Although electrolyte changes (e.g., hypokalemia) are common, they are impossible to predict with any accuracy. Hypokalemia predisposes to cardiac arrhythmias and should be corrected before anesthesia is induced.

Endoscopic removal of foreign objects requires a flexible endoscope and appropriate retrieval forceps. The animal should always be radiographed just before being anesthetized to ensure that the object is still in the stomach. Laceration of the esophagus and entrapment of the retrieval forceps in the object should be avoided. If endoscopic removal is unsuccessful, gastrostomy should be performed.

## **Prognosis**

The prognosis is usually good unless the animal is debilitated or there is septic peritonitis secondary to gastric perforation.

# **GASTRIC DILATION/VOLVULUS**

# **Etiology**

The cause of gastric dilation/volvulus (GDV) is unknown but may involve abnormal gastric motility. Thoracic confirmation seems correlated with risk; Irish Setters with a deeper thorax relative to width are more likely to experience GDV. Dogs with parents that had GDV may also be at increased risk. There are conflicting data regarding what predisposes dogs to GDV. Eating a large volume during a meal, eating once a day, eating rapidly, being underweight, eating from an elevated platform, being male, and advanced age seem to increase risk. Feeding dry food that is high in oil may also increase risk. GDV occurs when the stomach dilates excessively with gas (e.g., aerophagia, bacterial fermentation of carbohydrates, diffusion from the blood). The stomach may maintain its normal anatomic position (gastric dilation) or twist (GDV). In the latter situation the pylorus typically rotates ventrally from the right side of the abdomen below the body of the stomach to become positioned dorsal to the gastric cardia on the left side. If the stomach twists sufficiently, gastric outflow is obstructed and progressive distention with air results. Splenic torsion may occur concurrently with the spleen on the right side of the abdomen if the stomach twists sufficiently. Massive gastric distention obstructs the hepatic portal vein and posterior vena cava, causing mesenteric congestion, decreased cardiac output, severe shock, and DIC. The gastric blood supply may be impaired, causing gastric wall necrosis.

# **Clinical Features**

GDV principally occurs in large- and giant-breed dogs with deep chests; it rarely occurs in small dogs or cats. Affected dogs typically retch nonproductively and may demonstrate abdominal pain. Marked anterior abdominal distention may be seen later. However, abdominal distention is not always obvious in large, heavily muscled dogs. Eventually, depression and a moribund state occur.

## **Diagnosis**

Physical examination findings (i.e., a large dog with a large tympanic anterior abdomen that is retching unproductively) allow presumptive diagnosis of GDV but do not permit differentiation between dilation and GDV; plain abdominal radiographs, preferably with the animal in right lateral recumbency, are required. Volvulus is denoted by displacement of the pylorus and/or formation of a "shelf" of tissue in the gastric shadow (Fig. 32-4). It is impossible to distinguish between dilation and dilation/torsion on the basis of ability or inability to pass an orogastric tube.

#### **Treatment**

Treatment consists of initiating aggressive therapy for shock (hetastarch or hypertonic saline infusion [see p. 396] may make treatment for shock quicker and easier) and then decompressing the stomach unless the patient is asphyxiating, in which case the stomach is decompressed first. Gastric

decompression is usually performed with an orogastric tube, after which the stomach is lavaged with warm water to remove its contents. The stomach of dogs with dilation and many with GDV can be decompressed in this manner. Mesenteric congestion caused by the enlarged stomach predisposes to infection and endotoxemia, making systemic antibiotic administration reasonable (e.g., cefazolin, 20 mg/kg administered intravenously). Serum electrolyte concentrations and acid-base status should be evaluated.

The orogastric tube should not be forced into the stomach against undue resistance because it could rupture the lower esophagus. If the tube cannot be passed into the stomach, the clinician may insert a large needle (e.g., a 3-inch, 12- to 14-gauge needle) into the stomach just behind the rib cage in the left flank to decompress the stomach (which usually causes some abdominal contamination) or perform a temporary gastrostomy in the left paralumbar area (i.e., the stomach wall is sutured to the skin, and then the stomach wall is incised to allow evacuation of accumulated gas and other contents). After the animal is stabilized, a second procedure is performed to close the temporary gastrostomy (if present), reposition the stomach, remove the spleen (if grossly infarcted), remove or invaginate the devitalized gastric wall, and perform a gastropexy. Gastropexy (e.g., circumcostal, belt loop, tube gastrostomy) is recommended to help prevent recurrence of torsion and may be correlated with prolongation of survival. Another option consists of

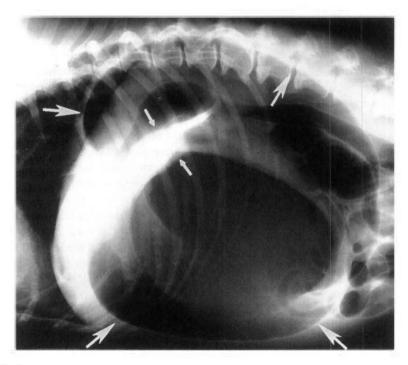

FIG 32-4

Lateral radiograph of a dog with gastric dilation/volvulus. The stomach is dilated (large arrows), and there is a "shelf" of tissue (small arrows), demonstrating that the stomach is malpositioned. Radiographs obtained from the right lateral position seem superior to those of other views in demonstrating this shelf. If the stomach were similarly distended but not malpositioned, the diagnosis would be gastric dilation.

immediately performing a laparotomy after decompressing the stomach but before stabilizing the animal. The decision as to whether to first stabilize the animal or immediately perform surgery is based on the condition of the dog at initial presentation and on whether the animal would be a considerably better anesthetic risk after stabilization.

If the dog has GDV (see Fig. 32-4), surgery is necessary to reposition the stomach; this is followed by gastropexy to prevent recurrence. This surgery should be performed as soon as the animal constitutes an acceptable anesthetic risk because torsion (even when the stomach is deflated) impairs gastric wall perfusion and may cause necrosis. Areas of gastric wall necrosis should be resected, or preferably invaginated, to prevent perforation and abdominal contamination. In dogs with gastric dilation without torsion, gastropexy is optional and may be performed after the dog is completely recovered from the current episode. Gastropexy almost always prevents torsions but does not prevent dilation.

Postoperatively, the animal should be monitored by electrocardiogram (ECG) for 48 to 72 hours. Lidocaine, procainamide, and/or soltolol therapy may be needed if cardiac arrhythmias diminish cardiac output (see Chapter 4). Hypokalemia is common and makes such arrhythmias refractory to medical control. Therefore hypokalemia should be resolved.

Prevention is difficult because the cause is unknown. Although preventing exercise after meals and feeding small meals of softened food would seem to be useful, there are no data to confirm this speculation.

# **Prognosis**

The prognosis depends on how quickly the condition is recognized and treated. Mortality rates ranging from 20% to 45% have been reported. Early therapy improves the prognosis, whereas a delay lasting more than 5 hours between onset of signs and presentation to the veterinarian's office, hypothermia at admission, preoperative cardiac arrhythmias, increased preoperative blood lactate concentrations, gastric wall necrosis, severe DIC, partial gastrectomy, splenectomy, and postoperative development of acute renal failure seem to worsen the prognosis. Although rare, gastric dilation may recur after gastropexy. Prophylactic gastropexy may be elected for animals believed to be at increased risk for GDV. Laparoscopy can be used to make prophylactic gastropexy a minimally invasive procedure.

# PARTIAL OR INTERMITTENT GASTRIC VOLVULUS

#### Etiology

The causes for partial and intermittent gastric volvulus might be the same as for classic GDV.

#### **Clinical Features**

Dogs with partial or intermittent volvulus do not have the life-threatening, progressive syndrome characterizing classic GDV. Although occurring in the same breeds as GDV, partial gastric volvulus usually produces a chronic, intermittent, potentially difficult-to-diagnose problem. It may occur repeatedly and spontaneously resolve; dogs may appear normal between bouts. Some dogs have persistent, nondistended volvulus and are asymptomatic.

## **Diagnosis**

Plain radiographs are usually diagnostic (Fig. 32-5). However, diagnosis may require repeated radiographs and/or contrast studies. Chronic volvulus will rarely be diagnosed endoscopically. It is possible, in rare cases, to cause a temporary gastric volvulus by manipulating the gastroscope in an air-distended stomach. Therefore the clinician must differentiate spontaneous from iatrogenic volvulus.

#### **Treatment**

If partial or intermittent gastric volvulus is diagnosed, surgical repositioning and gastropexy are usually curative.

# **Prognosis**

The prognosis is usually good once the problem is identified and surgically corrected.

# IDIOPATHIC GASTRIC HYPOMOTILITY

## Etiology

Idiopathic gastric hypomotility refers to an anecdotal syndrome characterized by poor gastric emptying and motility despite the lack of anatomic obstruction, inflammatory lesions, or other causes.

#### **Clinical Features**

Idiopathic gastric hypomotility has primarily been diagnosed in dogs. Affected dogs usually vomit food several hours after eating but otherwise feel well. Weight loss may or may not occur.

## Diagnosis

Fluoroscopic studies document decreased gastric motility, but diagnosis requires ruling out gastric outlet obstruction, infiltrative bowel disease, inflammatory abdominal disease, and extraalimentary tract diseases (e.g., renal, adrenal, or hepatic failure; severe hypokalemia or hypercalcemia).

#### **Treatment**

Metoclopramide (see Table 30-3) increases gastric peristalsis in some but not all affected dogs. Cisapride or erythromycin may be effective if metoclopramide fails. Diets low in fat and fiber promote gastric emptying and may be helpful.

## **Prognosis**

Dogs that respond to medical management have a good prognosis. Those that do not respond have a poor prognosis for cure, although they may still be acceptable pets.

FIG 32-5
Lateral abdominal radiograph of an Irish Setter with chronic vomiting caused by gastric volvulus that did not cause dilation. A "shelf" of tissue (arrows) demonstrates that the stomach has twisted.

# **BILIOUS VOMITING SYNDROME**

# **Etiology**

Bilious vomiting syndrome appears to be caused by gastroduodenal reflux that occurs when the dog's stomach is empty for long periods of time (e.g., during an overnight fast).

#### **Clinical Features**

Bilious vomiting syndrome usually affects otherwise normal dogs that are fed once daily in the morning. Classically, the pet vomits bile-stained fluid once a day, usually late at night or in the morning just before eating.

### **Diagnosis**

The clinician must rule out obstruction, gastrointestinal inflammation, and extraalimentary tract diseases. Elimination of these disorders, in addition to the history as described, strongly suggests bilious vomiting syndrome.

#### **Treatment**

Feeding the dog an extra meal late at night to prevent the stomach from being empty for long periods of time is often curative. If vomiting continues, a gastric prokinetic may be administered late at night to prevent reflux.

### **Prognosis**

The prognosis is excellent. Most animals respond to therapy, and those that do not remain otherwise healthy.

# GASTROINTESTINAL ULCERATION/ EROSION

#### Etiology

Gastrointestinal ulceration/erosion (GUE) is more common in dogs than in cats. There are several potential causes. Stress ulceration is associated with severe hypovolemic, septic, or neurogenic shock, such as occurs after trauma, surgery, and endotoxemia. These ulcers are typically in the gastric antrum, body, and/or duodenum. Extreme exertion (e.g., in sled dogs) causes gastric erosions/ulcers in the body and fundus, probably as a result of a combination of poor perfusion and high circulating levels of glucocorticoids.

NSAIDs (e.g., aspirin, ibuprofen, naproxen, piroxicam, flunixin) are a major cause of canine GUE because these drugs have longer half-lives in dogs than in people. Naproxen, ibuprofen, indomethacin, and flunixin are particularly dangerous to dogs. Concurrent use of more than one NSAID or use of an NSAID plus a corticosteroid (especially dexamethasone) increases the risk of GUE. The newer COX-2-selective NSAIDs (e.g., carprofen, dericoxib, meloxicam, etodolac) are less likely to cause GUE; however, GUE can still occur if these drugs are used inappropriately (e.g., excessive dose, failure to have an adequate washout period between use of different NSAIDs, concurrent use of corticosteroids). Use of NSAIDs in animals with poor visceral perfusion (e.g., those in cardiac failure, shock) may also increase the risk of GUE. Most steroids pose minimal risk unless the

animal is otherwise at increased risk for GUE (e.g., anoxic gastric mucosa due to shock or anemia). Dexamethasone, however, is clearly ulcerogenic when used at high doses.

Mast cell tumors may release histamine (especially if radiation or chemotherapy is being used), which induces gastric acid secretion. Gastrinomas are apudomas principally found in the pancreas. Usually occurring in older dogs and rarely in cats, these tumors secrete gastrin, which produces severe gastric hyperacidity, duodenal ulceration, esophagitis, and diarrhea.

Renal failure seldom causes GUE, but hepatic failure seems to be an important cause in dogs. Foreign objects rarely cause GUE, but they prevent healing and increase blood loss from ulcers. Inflammatory bowel disease may be associated with GUE in dogs, although most animals with this condition do not have these lesions. Gastric neoplasms and other infiltrative diseases (e.g., pythiosis) may also cause GUE (see p. 438) Tumors are especially important as a cause in cats and older dogs.

### **Clinical Features**

GUE is more common in dogs than in cats. Anorexia may be the principal sign. If vomiting occurs, blood (i.e., fresh or digested) may or may not be present. Anemia and/or hypoproteinemia occasionally occur and cause signs (i.e., edema, pale mucous membranes, weakness, dyspnea). Melena may occur if there is severe blood loss within a short period of time. Most affected dogs, even those with severe GUE, do not demonstrate pain during abdominal palpation. Perforation is associated with signs of septic peritonitis (see p. 476). Some ulcers perforate and seal over before generalized peritonitis occurs. In such cases a small abscess may develop at the site, causing abdominal pain, anorexia, and/or vomiting.

### **Diagnosis**

A presumptive diagnosis of GUE is usually based on finding evidence of gastrointestinal blood loss (e.g., hematemesis, melena, iron-deficiency anemia) in an animal without a coagulopathy. The history and physical examination may identify an obvious cause (e.g., stress, NSAID administration, mast cell tumor). Perforation may cause peritonitis and signs of an acute abdomen and sepsis. Because mast cell tumors may resemble almost any cutaneous lesion, all cutaneous masses or nodules should be evaluated cytologically. Hepatic failure is usually diagnosed on the basis of the serum biochemistry profile. Contrast radiographs are diagnostic for foreign objects and sometimes for GUE (Fig. 32-6). Ultrasonography sometimes detects gastric thickening (such as would be seen in infiltrated lesions) and/or mucosal defects. Endoscopy is the most sensitive and specific tool for diagnosing GUE (see Figs. 29-18 to 29-21) and, in conjunction with biopsy, can be used to diagnose tumors (see Fig. 29-20), foreign bodies (see Fig. 29-24), and inflammation that may cause ulcers. Endoscopic findings may also suggest a gastrinoma if duodenal erosions are found. Serum gastrin concentrations should be measured if a gastrinoma is suspected or if there are no other likely causes.

FIG 32-6

Contrast ventrodorsal radiograph of a dog with persistent vomiting. Note the small "sliver" representing retention of barium in the region of the pylorus (arrows). This area of contrast persisted on several radiographs. Endoscopy and surgery confirmed a large ulcer that had perforated and spontaneously sealed. This radiograph demonstrates how difficult radiographic diagnosis of gastrointestinal ulceration can be.

## **Treatment**

Therapy depends on the severity of GUE and whether an underlying cause is detected. Animals with suspected GUE that is not obviously life threatening (i.e., there is no evidence of severe anemia, shock, sepsis, severe abdominal pain, or severe depression) may first be treated symptomatically if the clinician believes that he or she knows the cause.

Symptomatic therapy (e.g., H<sub>2</sub> receptor antagonists, proton pump inhibitors, sucralfate, parenteral fluids, withholding food) is often successful. Eliminating the underlying etiology (e.g., NSAIDs, shock) is important, and any gastric foreign objects present should be removed. If appropriate medical therapy is unsuccessful after 5 or 6 days, or if the animal has life-threatening bleeding despite appropriate medical therapy, the ulcer(s) should usually be resected. The stomach should be examined endoscopically before surgery to determine the number and location of the ulcers; it is surprisingly easy to miss ulcers during laparotomy.

In animals with gastrinomas,  $H_2$ -receptor antagonist therapy is often palliative for months. Animals with high serum gastrin concentrations may require more potent and/or higher doses of  $H_2$  receptor antagonists (e.g., famotidine) or the more potent proton pump inhibitors (see Table 30-4).

Prevention of GUE is preferable to treatment, and rational NSAID and steroid therapy are especially important. Sucralfate (Carafate; see Table 30-5) and H<sub>2</sub> receptor antagonists (see Table 30-4) have been used in an attempt to prevent GUE in dogs receiving NSAIDs and steroids; however, there is no good evidence that these drugs are effective for this purpose in dogs and cats. Misoprostol (see Table 30-5) is designed to prevent NSAID-induced ulceration and is more effective than H<sub>2</sub> receptor antagonists or sucralfate. However, it is not uniformly successful.

# **Prognosis**

The prognosis is favorable if the underlying cause can be controlled and if therapy prevents perforation of the ulcer.

### INFILTRATIVE GASTRIC DISEASES

#### **NEOPLASMS**

## Etiology

Neoplastic infiltrations (e.g., adenocarcinoma, lymphoma, leiomyomas, and leiomyosarcomas in dogs; lymphoma in cats) may produce GUE through direct mucosal disruption. Gastric lymphoma is typically a diffuse lesion but can produce masses. The cause and significance of benign gastric polyps are unknown. They seem to occur more commonly in the antrum.

# **Clinical Features**

Dogs and cats with gastric tumors are usually asymptomatic until the disease is advanced. Anorexia (not vomiting) is the most common initial sign. Vomiting caused by gastric neoplasia usually signifies advanced disease or gastric outflow obstruction. Adenocarcinomas are typically infiltrative and decrease emptying by impairing motility and/or obstructing the outflow tract. Weight loss is commonly caused by nutrient loss or cancer cachexia syndrome. Hematemesis occasionally occurs, but leiomyomas seem to be the tumor most likely to cause severe acute upper gastrointestinal bleeding. Other bleeding gastric tumors are more likely to cause iron deficiency anemia even if gastrointestinal blood loss is not obvious. Polyps rarely cause signs unless they obstruct the pylorus.

## Diagnosis

Iron deficiency anemia in a dog or cat without obvious blood loss suggests gastrointestinal bleeding, often caused by a tumor. Plain and contrast imaging may reveal gastric wall thickening, decreased motility, and/or mucosal irregularities. The only sign of submucosal adenocarcinoma may be failure of one area to dilate (see Fig. 32-2, C). Ultrasound-guided aspiration of thickened areas in the gastric wall may produce cytologic preparations that are diagnostic for adenocarcinoma or lymphoma. Endoscopically, such areas may appear as multiple mucosal folds extending into the lumen without ulceration or erosion. Some tumors will be obvious endo-

scopically. When biopsy of such lesions is performed endoscopically, the sample must be deep enough to ensure that submucosal tissue is included. Furthermore, scirrhous adenocarcinomas may be so dense that the clinician cannot obtain diagnostic biopsy specimens with flexible endoscopic forceps. Mucosal lymphomas and nonscirrhous adenocarcinomas often produce GUE, and endoscopically obtained tissue samples are usually diagnostic. Polyps are usually obvious endoscopically, but a biopsy specimen should always be obtained and evaluated to ensure that adenocarcinoma is not present.

#### **Treatment**

Most adenocarcinomas are advanced before clinical signs are obvious, making complete surgical excision difficult or impossible. Leiomyomas and leiomyosarcomas are more likely to be resectable than adenocarcinomas. Gastroduodenostomy may palliate gastric outflow obstruction caused by an unresectable tumor. Chemotherapy is rarely helpful except for dogs and cats with lymphoma.

## **Prognosis**

The prognosis for adenocarcinomas and lymphomas is poor unless they are detected very early. Leiomyomas and leiomyosarcomas, if diagnosed relatively early, are often cured surgically. It does not appear to be necessary to resect gastric polyps unless they are causing outflow obstruction.

### **PYTHIOSIS**

## Etiology

Pythiosis is a fungal infection caused by *Pythium insidiosum*. This species is principally found in the Gulf coast area of the southeastern United States. Any area of the alimentary tract or skin may be affected. The fungus typically causes intense submucosal infiltration of fibrous connective tissue and a purulent, cosinophilic, granulomatous inflammation causing GUE. Such infiltration prevents peristalsis, causing stasis.

## **Clinical Features**

Pythiosis principally affects dogs, typically causing vomiting, anorexia, diarrhea, and/or weight loss. Because gastric outflow obstruction occurs frequently, vomiting is common. Colonic involvement may cause tenesmus and hematochezia.

## Diagnosis

Diagnosis requires serology or seeing the organism cytologically or histologically. Enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) tests are available to look for antibodies or antigen, respectively. Biopsy samples should include the submucosa because the organism is more likely to be there than in the mucosa. Such diagnostic biopsy specimens can be procured by way of rigid endoscopy; however, because of the dense nature of the infiltrate, a sufficiently deep sample can rarely be obtained by flexible endoscopy. Cytologic analysis of a tissue sample obtained by scraping an excised piece of submucosa with a

scalpel blade may be diagnostic; fungal hyphae that do not stain and appear as "ghosts" with typical Romanowsky-type stains are strongly supportive of a diagnosis. The organisms may be sparse and difficult to find histologically, even in large tissue samples.

#### **Treatment**

Complete surgical excision provides the best chance for cure. Itraconazole (5 mg/kg administered orally q12h) or liposomal amphotericin B (2.2 mg/kg/treatment) with or without terebinifin may benefit some animals for varying periods of time. Immunotherapy has recently become available, but critical evaluation of the efficacy of this therapy is not currently available

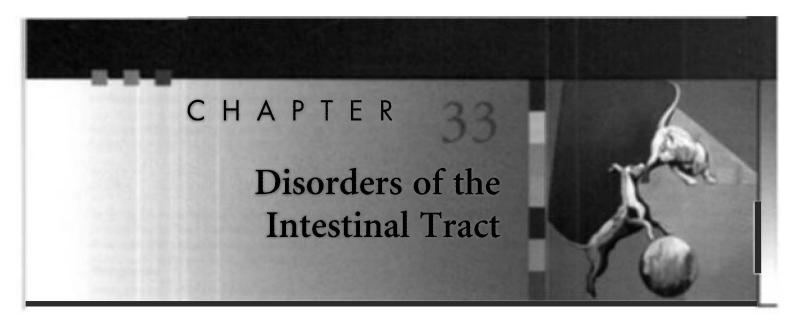

## **Prognosis**

Pythiosis often spreads to or involves structures that cannot be surgically removed (e.g., root of the mesentery, pancreas surrounding the bile duct), resulting in a grim prognosis.

## **ACUTE DIARRHEA**

# **ACUTE ENTERITIS**

#### Etiology

Acute enteritis can be caused by infectious agents, poor diet, abrupt dietary changes, inappropriate foods, additives (e.g., chemicals), and/or parasites. Except for parvovirus, parasites, and obvious dietary indiscretions, the cause is rarely diagnosed because most affected animals spontaneously improve, although supportive therapy may be needed.

#### **Clinical Features**

Diarrhea of unknown cause occurs commonly, especially in puppies and kittens. Signs consist of diarrhea with or without vomiting, dehydration, fever, anorexia, depression, crying, and/or abdominal pain. Very young animals may become hypothermic, hypoglycemic, and stuporous.

# Diagnosis

History and physical and fecal examinations are used to identify possible causes. Fecal flotation (preferably a centrifugal flotation using zinc sulfate flotation solution) and

direct fecal examinations are always indicated because parasites may worsen the problem, even when they are not the main cause. The need for other diagnostic procedures depends on the severity of the illness and on whether the risk of contagion exists. Clinically mild enteritis is usually treated symptomatically, with few diagnostic tests being performed. If the animal is febrile, has hemorrhagic stools, is part of an outbreak of enteritis, or is particularly ill, then additional tests (e.g., complete blood count [CBC] to identify neutropenia, fecal enzyme-linked immunosorbent assay (ELISA) for canine parvovirus, serologic analysis for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), blood glucose to identify hypoglycemia, and serum electrolytes to detect hypokalemia) are indicated. Abdominal radiographs and/or ultrasonography should be evaluated if abdominal pain, masses, obstruction, or foreign body are suspected.

#### **Treatment**

Symptomatic therapy usually suffices. The cause is usually unknown or is a virus for which there is no specific therapy. The goal of symptomatic therapy is reestablishment of fluid, electrolyte, and acid-base homeostasis. Animals with severe dehydration (i.e., ≥8% to 10% as determined by sunken eyes; fast, weak pulse; and marked depression; or a history of significant fluid loss coupled with inadequate fluid intake) should receive intravenous fluids, whereas fluids administered orally or subcutaneously usually suffice for patients that are less severely dehydrated. Potassium supplementation is usually indicated, but bicarbonate is rarely needed. Oral rehydration is sometimes useful in allowing home management of animals, especially when litters of young animals are affected. (See the discussion on fluid, electrolyte, and acid-base therapy in Chapter 30 for details.)

Antidiarrheals are seldom necessary except when excessive fecal losses make maintenance of fluid and electrolyte balance difficult, but they are often requested by clients. Opiates are usually the most effective antidiarrheals. Bismuth subsalicylate (see Table 30-6) is useful in stopping diarrhea in dogs with mild to moderate enteritis. However, absorption of the salicylate may cause nephrotoxicity in some animals (especially when combined with other potentially nephrotoxic drugs), and many dogs dislike the taste. Cats rarely need these medications. (See the discussion on drugs that prolong intestinal transit time in Chapter 30.) If antidiarrheals are needed for more than 2 to 5 days, the animal should be carefully reassessed.
